When Mulder, Rose, and Voit had made it highly probable that with the present form and modes of medication mercuric albuminate was the final modification of mercury in the system, and that as such it circulated in the organism, the question naturally arose whether or not these scientific facts could not be made of some worth in advancing the therapy of syphilis. Directing our attention to the liver, then, and considering the bile, its characteristic secretion, we know that the principal constituents of this bile are glycocholic acid and taurocholic acid. By treating these acids in a suitable way the former may be split up into cholic acid and glycocol, while the latter may be decomposed into cholic acid and taurin. We see then that cholic acid is common to both these constituents. It is a white, crystalline mass which may be recrystallized from solution in alcohol or in glacial acetic acid. This cholic acid is capable of forming with the positive elements, metallic salts, and cholates of the heavy metals may be obtained by reaction with the cholates of the alkali metals. In this manner mercuric cholate may be produced. This salt, which has the formula Hg(C24H30O5)2, is a yellowish white powder, not very heavy, insoluble in pure water but soluble in alkaline fluids and especially so in a solution of common salt. I believe that I am right in saying also that mercuric cholate is the salt of mercury most closely related to mercury albuminate. These two facts that it is a preparation, in which the molecule of mercury is not united with a heterogeneous acid, but to one normally present in the body and especially in that organ for which mercury has an especial affinity, together with the fact that it is so closely allied to the final form of mercury in the human economy, suggest two possibilities, namely:

First: Such a compound ought theoretically to be easily soluble in the digestive tract, readily absorbed, and possess qualities that would aid storage in the liver, normal distribution throughout the human system, and rapid and complete elimination.

Secondly: Mercuric cholate ought to be of espe-

cial value in the treatment of syphilis.

These ideas, suggested on theoretical grounds, are found by laboratory experimentation and clin-

ical experience to be facts.

Further, although Husemann classifies mercuric cholate as a mild corrosive, its action in the digestive tract, so far as observation has been made, would not warrant any emphasis being laid on this point. The intensity of the corrosive action of any salt depends upon the corrosive nature of the acid in combination. The characteristics of cholic acid would require us to lay stress on the word "mild" if we use the expression as I have just done, "mild cor-However, as all corrosive action can be completely done away with by the presence of some astringent, for medicinal use mercuric cholate is combined with tannic albuminate in the proportion of two parts tannin albuminate to one part of mercury cholate, and for short, the profession knows this combination as mercury albuminocholotannate.

It remains, then, for me, in closing briefly, to sum up the advance medical science has made in syphilitic medication as evidenced in mercury albuminocholotamate.

First and foremost, mercury albuminocholotannate permits a simple, easy, yet effective medication by the mouth alone. The internal treatment of syphilis, although it has not been very popular in Germany, has attained in France and England a certain monopoly of syphilitic medication.

Rollet says: "The internal application of mercury and its preparations is to-day the most popular

method of the therapy of syphilis."

Renaud, in a meeting of the Société de therapeutique, in Paris, declared: "On the strength of an experience of twenty years I own that I am compelled to uphold Fournier's opinion that the subcutaneous method of the mercurial treatment of syphilis cannot be adopted in general practice." It can only be recommended in a case with an intolerant stomach for internal applications, and even then the advantages are not very pronounced. The reason why the internal therapy of syphilis has not been universally favored so far was the lack of a nonobjectionable but energetically acting preparation. The following objections have been offered against the internal treatment:

It is not reliable, as thereby large quantities of mercury cannot be introduced into the body. The salts of mercury, which alone have been available, when taken internally produce local irritation of the alimentary tract, and the assimilation of the mercury

is irregular.

In America, internal medication for a long time has been practised, and is admitted to be the ideal method if we possessed, as I said early in this paper, a preparation of mercury that could be thus administered and at the same time be effective and easily controlled when once in the system. Mercury albuminocholotannate was at first put up in capsules, and in this form was used in Germany for a long time; now, however, the elaborate and accurate machinery of the manufacturing pharmacist has produced tablets that are stable, and it seems almost fabulous that the syphilitic now can carry his medication, more efficient than ever before, in a small vial in his pocket, and take his dose as if he were eating candy or a throat lozenge. Such, however, is the fact, as my cases which I will mention shortly will show.

Again, mercury albuminocholotannate permits the administration of mercury in maximum doses, re peated practically indefinitely, without harm or even discomfort to the patient. For instance, we know that mercuric bichloride contains 73.8 per cent. of mercury; mercuric cholate contains 23.3 per cent. of mercury, therefore the average dose of corrosive sublimate, or 1/6 grain three times a day, is equivalent to 11/20 grains of mercuric cholate, or a total daily dose of 1/2 grain of corrosive sublimate equals 1 13/20 grains of mercuric cholate. Now, mercuric cholate may be administered to the amount of 71/2 grains daily, or an equivalent of 21/4 grains of corrosive sublimate, nearly five times the maximum daily dose of that substance. When we think what severe intestinal lesions would be produced by a dosage which anywhere approached this, and then think that its equivalent in mercuric cholate may be administered ordinarily without any untoward symptoms, we realize that an ideal syphilitic medication has been approached, if not actually attained. It should be noted, however, that daily doses of 21/4 grains or 41/2 grains are usually sufficient to meet the requirements of successful medication. These

doses, clinical experience has shown, may be repeated practically indefinitely without causing any intestinal disturbance—neither pain, colic, or diar-

Another and third important point which I would notice is that the absorption and elimination is regular and rapid. I have not time to go into tedious detail, but these characteristics both experiments in the laboratory upon the lower animals and clinical experience in the case of human beings have proved to be facts. In all cases in which chemical examinations have been made, and they are many, the amount of mercury albuminocholotannate eliminated by the urine has always been in strict proportion to the amount administered by the mouth, and rises and falls in this eliminaiton always follow closely upon corresponding increases or diminutions in doses.

As a rule, I begin with a dose of 3/4 grain three times a day, and continue this amount for four or five days. On the sixth day I change to a 2½ grain tablet twice daily, making a maximum daily dose of 4½ grains. I continue this amount for some days, and then, according to the case, I give smaller tablets more frequently until I reach a maximum dose of 7½ grains daily. These tablets I administer invariably immediately after meals, as thereby I obtain the best effects.

I shall pass over the symptoms and progress of the disease, and simply mention that local symptoms were treated in the usual manner, while mercury albuminocholotannate capsules or tablets were given as specific treatment. Close observation shows that the action of this substance on the syphilitic process consists in an abatement of the symptoms, such as syphilides of the skin, plaques in the mouth, condylomata of the genitals, etc., fully as well if not better than is the case by an inunction treatment or injection cure with soluble salts. The skin and mucous syphilides disappeared on an average in from twenty to thirty days. Seventy per cent., that is, twenty of my cases, were primary infections, of which seventy-five per cent. treated with this preparation showed a prompt and quick diminution of symptoms. The results were supremely satisfactory. In twenty-five per cent. of the cases the action was slower, from one to two months. The remaining thirty per cent, of my cases, all of which were old infections, some of which had had a number of so called "cures," and were now suffering from relapses, all responded to the action of mercury albuminocholotannate, some promptly and satisfactorily, some less promptly, while in two cases, that is, seven per cent. of the total number of cases, the effect was only slight. These cases were patients who had received rather radical and rapid treatment, but notwithstanding suffered with obstinate plaques, psoriasis of the hands, etc. I believe that Professor Boss is right in his opinion that the too rapid repetition of the cures and the consequent saturation of the body with mercury is a reason for the apparently weak effect of mercury albuminocholotannate in cases like

Regarding secondary effects produced by mercury albuminocholotannate, about ten per cent, of the cases acquired a slight stomatitis consisting of redness and swelling of the gums. Treatment was suspended for only three or four days, after which time

it was renewed and continued with satisfactory results. With Wolff I consider that an appearance of a slight stomatitis is the best sign of an effective mercurialization. For it seems reasonable to suppose that the antisyphiltic effect of a mercurial preparation must correspond with the mercurial effect; if the latter is lacking, the former will not be evident; in other words, a preparation that is not capable of producing a mercurial effect will not be of great influence on the syphilitic process. As regards the effect of mercury albuminocholotannate on the digestive tract, I can say that it produced in most cases no disturbance at all and in none any disturbance which necessitated an interruption of the cure. This I consider to be a highly satisfactory state of affairs.

As the first cure is of great importance for the future course of syphilis, it is necessary to treat the patient with mercury albuminocholotannate for at least from ten to twelve weeks. The average quantity for a patient will be from five drachms to one ounce (20 to 30 grammes). If this prescription be adhered to it will be seen that relapses after such a treatment are not more frequent than after an inunction or injection cure. Besides the cure does not interfere with daily life and is not weakening or dangerous to the patient; on the contrary, with its use the general health of the patient never gets run down. Great importance should, of course, be attached to general hygiene, i. e., a quiet, regular mode of life on the part of the patient, with sufficient sleep and adherence to a special diet. Nourishment should be plentiful and wholesome, but unirritating to the intestines. Consequently, fresh fruit, acids, salads, highly seasoned food, and fats should be prohibited. Of alcohol only a little claret should be permitted for dinner and supper. Care of the teeth and mouth is of the utmost importance so that stomatitis may be avoided. The skin should be treated with warm baths. The urine should be under continual examination before, during, and after the cure. The general treatment, of course, should be assisted by local treatment with the customary ointments, powders, etc., as may be necessary.

35 CHAUSSEUSTRASSI.

PRELIMINARY REPORT ON THE VACCINE TREATMENT OF ATROPHIC RHINITIS (OZ ENA).

By Ross Hall Skillern, M. D., and F. Burvull-Holmes, M. D., Philadelphia.

(Ross Hail Skillern, M. D.)

CASE I.—Shortly after reopening my office in the fall of 1007 a little patient was referred to me suffering with atrophic rhinitis. Almost as soon as he had entered my door the diagnosis was made possible on account of the peculiar feetor of this disease which was disseminated through the air. As the patient was a handsome boy of eight years and the parents people of some position, my feelings were certainly not elated when I recalled the numerous observers and scientists, particularly in Germany, who had devoted the best years of their lives investigating this disease with the most disappointing results as far as a curative treatment was concerned. Certain individual cases had been reported cured by new methods, but these methods appear only to have been successful in the hands of their authors.

To return to the patient, examination revealed a severe case of rhinitis atrophicans with all its attending symptoms (crusts, pus, foctor, etc.) and apparently in the height of its course. I frankly reviewed the status præsens of the attitude of the profession toward the disease to the parents, impressing upon them the importance of carrying out home treatment faithfully, for without this it would be uscless to institute and continue treatment at the office. I also stated that under appropriate continued office and home treatment the child would apparently improve, but should for any reason the treatment be suspended a rapid return to the old condition would surely occur and must be expected. As the child had never before been examined, the mother was exceedingly depressed, not having suspected the seriousness of the disease; however, she readily accepted the inevitable and placed the boy under treatment. The patient now presented himself thrice weekly for treatment, during which time thorough examinations were made for any sinus involvement, but without The patient did improve as far as the crusts and fector were concerned, but it subsequently developed that this improvement was only apparent. The treatment, which consisted of thorough cleansing with hydrogen peroxide, followed by warm normal salt solution until no trace of crusts or pus could be observed, and the entire nasal mucosa painted with a solution of actione and chloretone in liquid petrolatum, was continued for nine weeks, when it was interrupted by some slight illness of the patient which necessitated his confinement to the house for about ten days. As the home treatment was also discontinued at this time, the condition of the patient at the end of the attack was precisely the same as when first brought for examination. Under these circumstances it was selfevident that the local treatments were of temporary benefit only and might have been continued indefinitely with no real permanent curative value.

Recognizing the utter futility of bringing about a cure from a local point of treatment, I turned to the bacteriological standpoint of the disease, which although having been thoroughly investigated by our German colleagues with little or no success (therapeutically speaking), nevertheless offered the only hope in this particular case. The opsonic index theory was explained to the parents, with its possibilities, and their sanction obtained to try it with their boy. billities, and their sanction obtained to try it with their boy. I collected and reread the investigations of E. Fränkel (1), Löwenberg (2), Klamann (3), Thost (4), Hajek (5), Abel (6, 8), Paulsen (7), Fricke (9), Stein (10), Klemperer and Scheier (11), Strübing (12), etc., and found that the results of these observers were practically identical. A bacillus similar to the pneumonococcus of Friedländer was always present in large quantities together with an encapsulated bacillus first described by Abel (6). The habitat of the latter appeared to be in the membrane which formed between the crusts and the mucous membrane. Abel seems to have been successful in separating these bacilli and cultivating the latter in pure culture, and stated it to be the real cause of the disease, not so much from the direct action of the bacillus on the tissue as through the toxine

which it eliminated.

Acting on the theory of Abel, I consulted with my friend Dr. E. Burvill-Holmes regarding the advisability of trying the vaccine treatment with this case. It was decided that it might be feasible and certainly could do no harm, and he consented to take up the work from the bacteriological standpoint. On the next visit of the patient I washed the nose out with a normal salt solution, removed, under all possible antiseptic precautions, a large crust from the surface of the inferior turbinate, and made a smear culture on agar with a piece of the false membrane obtained from beneath the crust. Dr. Holmes took the tube in charge, and in a few days reported that the culture had grown well. The predominating organism was a coccus similar to the pneumonococcus of Friedländer; the bacillus of Abel was also present, though in smaller quantities. After numerous cultures a comparatively pure culture of the latter bacillus was obtained. It was decided to plate these organisms and procure absolutely pure cultures, thereby making it possible to obtain the opsonic index of the patient for both varieties. This was attempted with ordinary and later with special media, failure being the result in every case. There was no difficulty in obtaining pure cultures of the coccus, our point of view, for we had accepted it as the true cause of the disease, resisted every attempt at culture. It appeared to thrive badly on all sorts of media, being finally

choked by the overgrowth of other organisms. Under these circumstances Dr. Holmes suggested making a vac-cine from the combined culture of a serum from a pure culture of the bacillus of Abel, which seemed, at least for the present, impossible. The serum vaccine was made in the strengths mentioned by Dr. Holmes. I discontinued local treatment with the patient at once in order to overcome any possible doubt that might arise as to the therapeutic value of the vaccine. Injections were given in the arm at first twice weekly, no inflammatory reaction occurring. The patient's appetite increased at once, and the features assumed a much better color. After two weeks there was marked diminution in the size of the crusts and the nasal secretions appeared to be much thinner and more miscible with water. (The nose being washed out at each visit with a warm normal salt solution.) About this time a gradual diminution of the fœtor occurred, which was not only substantiated by the parents but by their friends as well. At this interesting stage the little patient contracted a disease resembling scarlet fever (such a diagnosis was made by the family physician), which brought the treatment to a sudden close. About two months after the onset of the fever I received a communication from the mother stating that the boy was now convalescent and the nasal condition had retrograded to such an extent that it was as bad as ever. She further stated that it gradually became worse, and did not reach the old stage for several weeks after the treatments were suspended, and expressed the desire to resume treatment at the earliest possible moment.

The promising results in the previous case prompted me to test this method in a case which had proven absolutely hopeless to other forms of treatment. The history briefly is as follows:

Case II.—Miss J. L., thirty years, atrophic rhinitis since childhood, all symptoms relative to the disease present, i. e., crusts, fœtor, purulent discharge, gradual deafness, severe tinnitus, etc., had been under treatment with various physicians for twenty-five years. Condition steadily grew worse.

Examination: Inferior and middle turbinates on both sides greatly atrophied, nearly all of the anterior wall of the sphenoid being visible. Crusts were present in the choanæ and middle nasal fossa, purulent discharge from the right side. Entire Schneiderian membrane appeared glazed and covered with the usual secretion. Needle puncture brought a large quantity of foetid pus from the right antrum, while

left antrum was negative.

The patient had been under my care for over a year with temporary amelioration of the symptoms. I had already advised a radical operation on the maxillary antrum some months before commencing the vaccine treatment. A portion of the membrane was taken from the nose and a smear culture on blood serum made, which Dr. Holmes smear culture on blood serum made, which it is thook in charge, isolating the Bacillus mucosus as before, but was again unable to grow them in pure culture. However, a serum was made of the mixed culture to the strength mentioned by him. These injections were given twice weekly, all local treatment, with the exception of cleansing with normal salt solution, being dispensed with. After five injections improvement was noted, the crusts being much smaller and allowing themselves to be more readily removed. The collection of inspissated mucus which formed in the choanæ and was so annoying to the patient became less and less. There was undoubted diminution of the fector, and the general health improved. This treat-ment was continued until she had taken fourteen injections, when a sudden change for the worse set in. The disease gradually began to assume its old condition, crusts became larger, and the fector reappeared. The patient complained of constant nausea and said she "felt as though she had swallowed a quantity of secretion from her nose." The treatments were discontinued and the patient lost sight of. About three months after this time she again appeared, requesting treatment, saying that she had never felt so well as when under the vaccine treatment and would rather endure the nausea than be tormented with the nasal condition.

At the present time she is again under treatment and has been benefited even past the stage of her first improvement. The injections are now being given in doses fifty per cent. less than formerly, and once every seven or ten

days according to symptoms

I am perfectly aware that the report of these cases in themselves contains little of value from a scientific

point of view on account of the inability to show definite results. However, it seems to me to bring out several points hitherto unpublished. In Case I the improvement was so marked that I felt assured a complete cure would result, when the treatments were suddenly discontinued through the patient's acquiring scarlet fever. Personally I do not believe this was scarlet fever, but a condition due to the vaccine being used either in too large doses, or too frequently, or both. While the attending physician suspected this condition he nevertheless appeared to be quite reticent about the case, and further details were unobtainable; however, the child recovered in two or three weeks. The mother consulted me some weeks later concerning the case, and stated that the old condition had returned, but not with the same severity, the child having kept quite well through the attack of fever.

Case II did not present the same possibilities for therapeutic success as Case I, owing to the length of time the disease had been present (over twenty-five years). The injections, however, brought about a favorable reaction in a surprisingly short length of time, the greatest relief being in the diminution in the amount of tenacious mucus which formed in the choanæ. The appetite and general condition also improved; the aural symptoms, however, remained unchanged. I am perfectly certain that the injections were either too frequently given or the dose too large in this case. As neither of us could determine the proper amount to administer except by experiment, the matter remained naturally one of guesswork.

It is, of course, impossible to draw reliable conclusions from two cases, although from the behavior of these under vaccine treatment I think it only fair to hope that this method offers possibilities which heretofore have not presented themselves in the treatment of this affection. If pure cultures of the Bacillus mucosus capsulatus could be obtained (I feel assured this will be accomplished in the near future) I believe the successful treatment of rhinitis atrophicus fætidans would, indeed, be a thing of reality.

(E. Burvill-Holmes, M. D.)

Whether or no any microorganism is the specific ætiological factor in rhinitis atropica is still a debated question. The weight of opinion, however, is probably to the effect that bacteria only play a secondary rôle and are of no pathological significance. Indeed, E. Frankel (1), who first discovered the Bacillus ozana-the organism considered by most of those who hold to the microbic origin of the disease to be the causative factor—denied the organism the power of inducing the true atrophic process, but the fœtor solely. However, three years later Löwenberg (2), to the contrary, asserted, although he could not prove his assertions, being unable to isolate and grow the organism in pure culture, that the entire process, fœtor included, was due to this mi-Thost (4) was of the same opinion as Frankel, while Abel (6 and 8), who in 1893 and 1895 investigated the subject extensively, satisfied himself at least that the Bacillus mucosus. as he called it, was the specific cause of ozænæ. Paulsen (7), a contemporary of Abel, was equally positive

on this point, basing his argument and belief on the constant presence of this organism in the diseased areas. In all of the fifty cases which he studied, he was able to demonstrate it. Strübing (12) became a proselyte to Abel's views also, and not merely because of the presence of the organism in his cases, but because he alleges to have actually reproduced a typical case of the disease, by inoculation, in a man dying of consumption. Dreyfus and Klemper (13) attempted to corroborate Strübing's result, but they were less fortunate. They inoculated two cases, neither of which was successful.

But it is not only to the Bacillus ozana-an organism considered by many bacteriologists as identical with many others that have been described. prominent among them the Bacillus Friedländerthat the disease under discussion has been attributed. Thus Symes, quoted by Flatov (14), regards the affection as a chronic form of nasal diphtheria, since in thirty-four per cent. of his cases he found a bacillus which morphologically and culturally corresponded to the Klebs-Loeffler bacillus. Moreover, he justifies himself as to the correctness of his view by affirming that the horrible affliction will sometimes yield to treatment by diphtheria antitoxine, when all

other means have proved futile.

In the treatment of our two cases, the writers assumed for experimental purposes solely that an organism was the causative factor, and since vaccine therapy had proved of indubitable value in the treatment of certain infections heretofore rebellious or incurable, the thought suggested itself it might be efficacious in this disease, which to the present time has baffled the most skilled and experienced rhinologists. At the outset it was proposed to isolate, if possible, the several organisms reputed to be the infective agent, and with the respective vaccines made from them, to inoculate the patients, controlling the injections by opsonic readings. A definite time was to be accorded to the treatment by each vaccine, a different one to be used in the event of failure to obtain results from a prior one.

Smears from portions of the thick, tenacious pus. washed in several changes of sterile normal salt solution, were first of all stained and microscopically examined. Both cases singularly revealed for the most part similar organisms. Predominant was a large bacillus showing a capsule and in hanging drop nonmotile, perhaps and probably the Bacillus ozænæ. Another that was quite numerous was one that morphologically resembled the Klebs-Læffler bacillus. Streptococci were also demonstrable, in addition to other unidentified bacteria. From the same portion of this exudate culture tubes of agar agar, blood agar, blood serum, nutrient bouillon, and litmus milk were inoculated. Examined at the end of twentyfour and forty-eight hours, the blood agar, bouillon. and milk tubes showed the growth of all the above specified organisms, the large bacillus being apparently absent from the agar agar and blood serum media. An attempt was now made to isolate the bacillus assumed to be the bacillus of Frankel and Abel. Several plates of blood agar, glycerin agar. and agar agar, were made and incubated at 37° C... but despite many trials the bacillus eluded capture, The patients who had been informed of and who had signified their willingness to submit themselves to the method of treatment were becoming impatient

at what they construed inexcusable delay, so that further attempts had to be abandoned. In lieu, then. of inoculating them with a single organism, we decided—unscientific as it probably was—to administer a "miscellaneous" vaccine, or, in other words, a vaccine composed of all the bacteria. To this end one out of several nutrient bouillon cultures, one in which the bacillus appeared to be in excess, was selected, and from this the vaccine was prepared, the death of the organism being brought about by their subjection to a temperature of 57° C. for one hour. No attempt was made, for obvious reasons, to compute the number of bacteria per c.c., so that the unit of dose utilized was the milligramme, or more properly, the microlitre. The guide to increase or decrease of dosage was controlled by clinical symptoms alone.

The initial dose was for the vounger patient 0.5 microlitre, for the older I microlitre, diluted with normal salt. This dose was administered biweekly and increased bimonthly providing no contraindications arose, each increase being 0.5 and I microlitre, respectively, for the two individuals.

2030 CHI S. M. C. STRELL.

Though all are familiar with this most common malady, yet the simple fact of its being possibly the most common of all diseased conditions met with, its careful study and investigation is too often overlooked. Again, it is one of those ailments we have always with us and we are too prone to accept it as a necessary evil. Though I will endeavor to treat this subject fairly from all sides, yet, as the public have learned that most persistent headaches are due to eyestrain, it is to the oculist a large proportion ily physician has been first consulted; the patients cured by him we do not see, while it is those not responding to general treatment that he refers to the specialist. Therefore, it is natural for the specialist to look at these troubles through his own glasses, however broad he may wish to be.

In every case of persistent headache, the most complete history, family and personal, should first be elicited with the most searching examination for all signs tending to connect the symptoms with any disease. Headache is one of the earliest and most frequent symptoms of several of the most serious pathological conditions. Mayer says: "In taking the history of a patient, many important factors may be elicited; a previous infectious disease that might have left an inflammation of one of the cranial sinuses, a trauma that might have evoked a chronic meningitis or an abscess or cyst, or an hereditary history that would make one think of migraine or latent or psychic epilepsy. The occupation might reveal the source of a toxic headache, the habits an alcoholic, nicotine, or sexual origin for it; or, again, we may find the environment of the patient is at fault, too many business worries, living in too close quarters, sitting constantly near a light, having constant worries or anxieties in the family circle, living irregularly, working late at night or eating improperly." Find the nature of the pain, its location, its duration, the time of occurrence, nature of work done preceding it, what aggravates and what relieves it, its connection with any other symptoms of any other organs, age, etc.

In this paper I shall use much material from a symposium by Dr. S. D. Risley, Dr. E. E. Mayer, Dr. J. C. Wilson, and Dr. B. A. Randall, of Philadelphia, each of whom treats it from its own special standpoint, thus including every side of the question. (Pennsylvania Medical Journal, December, 1907.)

Headaches may be classed:

I. Those due to diseases of nervous system: Pressure headaches, hydrocephalus, tumors, abscesses, cysts; inflammatory headaches, meningitis, purulent tuberculosis, pachymeningitis, epicranial myositis; circulatory headaches, anæmia and hyperæmia, arteriosclerosis, vasomotor: traumatic headaches; reflex headaches; psychic headaches, hypochondria, neurasthenia (exophthalmic goitre), hysteria, epilepsy; and habitual headaches.

2. Special senses: Eyestrain, nasal or ear dis-

3. Gastrointestinal: Deranged liver, constipation,

4. Kidney diseases.

- 5. Constitutional diseases: Anæmia, chlorosis, diabetes, leuchæmia, syphilis, rheumatism, malaria.
- 6. Toxics: Drugs, lead, nitrites, alcohol, etc.
- 7. Infections which include some of the above

8. Rheumatism of the scalp.

Under the first group, the organic headaches are those due to intercranial disease, usually more constant in their symptoms. Brain tumor has a deep boring pain. The pains of tumors or abscesses are usually more localized, while that of meningitis is more diffused and excruciating. The eye conditions, especially those seen with the ophthalmoscope, help in arriving at a conclusion. In epilepsy, usually the other symptoms accompany it. Those due to cerebral concussion or from injuries to the head may be localized or diffuse, usually severe and protracted. There is often tenderness on percussion, mental symptoms, lack of concentration, memory affected at times, vertigo, tinnitus, etc., also eve symptoms. In meningitis there will be vomiting without nausea, hyperæsthesia, delirium, vertigo, intolerance to light, etc. Rigidity of neck muscles with these symptoms indicates cerebrospinal meningitis. Tuberculous meningitis is often first indicated by intense paroxysmal headache, vomiting without nausea, constipation, and mental irritability.

The sensory nerve supply of the dura in the anterior three fourths of its extent, that of the falx and probably that of the tentorium are derived from the trigeminus, while the dura mater of the posterior fossa is supplied with sensory fibres from the vagus. The trigeminus is the nerve of sensation to the scalp as far back as the vertex, while the posterior branches of the upper four cervical nerves supply the muscles and the skin of the back of the neck and the occiput. Headaches are due to some changes affecting these nerves, either disease, pressure, or

circulatory changes.

The circulatory headaches are diagnosticated from the condition of the vessels, the anæmic being relieved by a recumbent position; the congestive have the throbbing full sensation. These are characterity, resulting from powder smoke. There is usually a congestion of the skin vessels, a flushed face, etc

The neurasthenic headache is very frequent in the morning, and can be arrived at only by exclusion. Unfortunately, we are prone to put too many in this class, or in Butte we find the altitude a convenient and inexhaustible refuge for those cases in which we fail to find the true cause. Hysteria has the circumscribed boring pain (clavus).

The habitual headaches will probably in time be classified otherwise, but at present, with most painstaking examination, some few headaches still re-

Of those due to the special sense, in fact, of all causes, eyestrain is the most frequent and constant of all persistent headaches. Dr. Risley has so well stated several definite conclusions, that I will use his words:

- 1. That ocular disease or anomalies of the ocular apparatus are in a large group of patients the sole and suf-
- 2. That abnormal visual conditions may be the unsuspected cause; therefore, that the absence of symptoms obviously referrable to the eyes does not exclude them as an ætiological factor in headache
- That, notwithstanding the congenital origin of many ocular anomalies, the sudden onset of headache coming on during or after middle life, or after attacks of acute dis-case, or during the ravages of some general dyscrasia, does not exclude the eye as an ætiological factor
- of headache and a considerable group of associated symptoms can be positively excluded only in the proved absence of ocular disease, or after the most painstaking correction of any existing error of refraction or abnormality of binocular balance.
 - 5. That, in many cases, prolonged eyestrain sets up

pathological states in the fundus oculi which require, like the cause; therefore, immediate relief of symptoms is not always to be expected.

That the existence of some general affection, e. g., as the immediate cause of an associated headache since the accompanying ocular disease, e.g., iritis, choroiditis, glaucoma, etc., may be the direct cause of the pain in the head, to relieve which local treatment also will be required.

7. That the existence of congenital ocular defects is especially prone to be the occasion of headache and other reflex neuroses in individuals with impaired vitality, whether inherited or acquired by faulty living or by daily told in a had hyging; environment.

Now, if all patients with eyestrain had head-aches, and all showed localized symptoms as dee. g., the myope, who is known to every one as near sighted, and most people who have red eyes, inflamed lids, very high degrees of hyperopia, or astigmatism may go on without ever, or at most only an which has never been even suspected, often produces ances. Thus, in this city at least, it is to be noted that the majority of the former class first buy glasses in the shops, while the great majority of the oculist's

Many people living out of doors or doing rough work, with good light, fresh air, abundant exercise, experience no trouble; change their vocation to that of constant close work indoors, often facing a light, all conditions changed, and a few minutes' work brings on headache. It is often difficult to convince these people that abnormal eyes, with which they have probably been born, are now the

cause of all this trouble.

The location of pain is usually in the forehead. back of the head, back of eyeballs, or in the temples. There is pain in the occiput, especially if the extrinsic muscles are involved. The pain back of the eyeball or optic nerve. This pain often shoots back to the neck and even to the shoulders. These headaches may subside or gradually increase, accompanied by nausea, intolerance to light and noise. Incapable of work, the person takes to bed with so called bilious, sick, or nervous headache; here, a few days' rest in the dark, and the patient is restored for a new start. I recall a female typesetter, treated for years for indigestion till the physician referred her to an oculist. She began with these symptoms, growing gradually worse till about Saturday, when she would begin vomiting, went to bed in a dark room, was sick over Sunday, and ready to start work on Monday.

These headaches usually come on after reading, sewing, or near work, or are aggravated by it. They are also common after shopping, riding on the car or train, or after the opera; usually worse in the afternoon or evening and gone in the morning. Again, they may so disarrange the mental condition that sleep is disturbed, and patient wakes in the morning with tired feeling and diffuse headache. These symptoms may be first noticed after some

disease which has lowered the vitality. Again, they are very frequent in business men about the age of forty-five, who attribute the symptoms to business worry and fail to assign their troubles to the true cause—loss of accommodation.

In children, chorea, nervousness, cross eyes, etc., often first direct the attention to the eyes.

Dr. Gould has so admirably demonstrated by the lives of so many eminent men, Huxley, Darwin, etc., what the world has lost by the failure to recognize the cause of their depressing headaches.

That glasses are being worn by patients is unfortunately no positive evidence the eyes are not the cause. In these cases, besides the general nervous condition of the patient, the ciliary muscle is always in a condition of tonic spasm and without the perfect relaxation of this spasm, which is often very difficult, glasses cannot be properly fitted. any muscle that has been in a fixed position more or less for years, suddenly relax it, and what is the resulting sensation? Try carrying a pail of water or bandage your arm in a fixed position for only a short time and experience the pain when it is re-laxed. Thus with the eye, after the most thorough and perfect examination, on this account the patient will usually refuse to wear the glasses, without considerable argument; in fact, some cannot. Then they must be changed from time to time to suit the case. Again, there are the complications, say hyperopia with astigmatism. Without the most exacting work in detail, with cross checking your own work, you may over correct one and under correct the other, and vice versa. All the spasm may not be relaxed or it may have been irregularly relaxed; the eye muscles may be at fault (heterophoria), or the eyeball may be rotated on its own axis (cyclophoria). Again, suppose all the correction is perfect, glasses perfectly fitted; the eye is only one of the most complicated organs and part of a most complicated body comprising a physical and psychical whole, thus proper prescribing of glasses becomes one of the most difficult of all surgical procedures. Yet, when it has been accomplished, there are but few headaches under this class that will not be immediately and permanently cured.

Headaches due to the nose are but beginning to receive attention. There is generally a pain over the root of the nose or brow, may be back of an eye or frequently diffuse. These are always worse if the patient gets an acute cold in the head, and careful questioning may elicit a history of a severe attack lasting for days being suddenly and completely relieved following an acute discharge of fluid from the nose or throat. These pains are more or less persistent with acute exacerbations, recurring often daily at the same hour. They are due to an irritated condition of the mucous membrane, pressure of middle turbinate against the sæptum, or to some irritation in some one or more of the sinuses, all of which are lined with an extremely sensitive mucous dental origin, so in all cases the teeth should be investigated. Spraying the nose with some sedative and vasomotor constricting drugs will temporarily relieve the congestion, thus the pressure, and afford drainage and relief for a short time. If acute, this

may cure it, otherwise the obstruction must be removed and free drainage given to the diseased sinuses. Polypus is the overlooked cause of some prolonged depressing headaches; these are frequently accompanied by asthma, which should always direct attention to the nose. Adenoids should be looked for in children as the primary cause of secondary diseases producing headaches.

Headaches from ear disease are usually localized, and may give rise to cerebral symptoms, this being the most frequent cause of epidural abscess.

Headaches due to abnormal pelvic conditions are most frequent in the top of the head and have associated history.

Those due to conditions of stomach, liver, and bowels are usually frontal with somnolence and vertigo; may be temporary blind spells; this class might also include some of intoxication.

Those of kidney diseases will not be overlooked if examination has been complete. These are intense, often continuous with exacerbations. They occur in uraemia and diabetes.

Syphilitic headaches are often worse at night up to a late hour, then subside, but this is not necessarily so. Tumor symptoms may be present.

Rheumatism is more likely to be in the scalp muscles and tender on pressure. Chlorosis, anemia, leuchæmia, malaria, smallpox, febrile diseases are all accompanied by severe headaches at times.

The toxic and infectious headaches are to be diagnosticated after a careful history as to occupation, habits, etc. Do not forget wood alcohol in varnishes; arsenic may be excessive in wall paper; lead in paints and printing; opium, chloral, or an excess of the coal tar preparations taken to relieve headaches result in aggravation. Coffee, tea, alcohol, etc., are also in this class.

As to the cure, first, if the cause is ascertained, the method is clear in the majority of cases. Social and business conditions must be considered; mode of living, diet, habits are of first importance. If due to eyestrain and eye fatigue, rest the eyes. As no one will do this, then relieve the excessive accommodation by correcting lenses. Often where no error exists, a convex lens for near work, takes off much of the excessive burden. A prominent attorney, in this State, who had to abandon his work after many fruitless attempts to get glasses, owes his present success to this over correction, so to speak.

Sending patients away changes their mode of living, and the treatment at the springs aids in elimination, while the mental and business relations are changed; thus habitual headaches are removed, but first all local diseases must be eliminated.

For the immediate relief coal tar products should be given with discretion; opiates very seldom if ever, better almost never. Sodium bromide, Indian cannabis, hyoscyamus, and gelsemium relieve many neurotic and congestive headaches. Atropine relieves engorged mucous membrane. Electricity in its various forms has its use in neurological cases. Tonics and laxatives relieve as a rule. In short, to repeat, if the proper diagnosis can be made, in every case, which is beyond the ability of any one man, there will remain few if any that will not be cured.

PNEUMONIA: ONE METHOD OF TREATMENT.*

By E. P. Tompkins, M. D., Roanoke, Va.

One raw, damp December day, with half thawed snow covering the ground, I encountered a young man, L. R., out funning. I noticed that he wore thin shoes and that they were thoroughly soaked with water. This was about I o'clock. At a quarter to 9 I was hastily summoned to his bedside. At 9 o'clock I reached him. I was told that he came in at nightfall, having spent the afternoon tramping the fields and loafing at a country store. He ate a light supper and went to bed at 8 o'clock feeling as well as usual. Before he could get to sleep he had a chill, followed in a little while by a severe pain below the left nipple. Fearful of pneumonia, he had promptly summoned me. His diagnosis, as far as one may judge from physical signs and symptoms, was correct.

He was a fine specimen of manhood physically, hale, hearty, robust, of good habits (not an alcoholic), about twenty years of age, and had never been sick before. His temperature when I reached him was nearly 103° F., and he was semi-delirious, which condition rapidly advanced to active delirium. Pulse full and bounding, face flushed; slight, hacking, suppressed cough, with frothy expectoration, which in another hour was gelatinous, and decidedly streaked or rather mixed with blood. Physical examination showed only slight dulness over the seat of pain.

Under my direction half a dozen bricks were at once procured, and placed on the fire; at the same time a kettle of water was put on to heat. When the water was boiling, water was put on to heat. When the water was boiling, and the bricks about red hot, they were placed in the water and allowed to remain until ebullition ceased, each one then wrapped in a cloth, and placed in the bed alongside the patient's body, and over him a number of blankets. Over the region of pain was put a flannel cloth saturated with oil of turpentine, over this a folded newspaper. Internally was administered a tablet of calomel and sodium hydroxide. half a grain each, one every two hours till four doses. Alternating with this, hour by hour, a tablet containing aconite, two minims; tartar emetic, one fortieth grain; ipecac, one eighth grain, morphine sulphate, one twentieth grain, to be given till further notice. In ten minutes the patient was trying to throw the covers off, and it took the combined efforts of four men, by main force, to hold this able bodied, delirious fellow in bed. He succeeded in yanking off the turpentine cloth, and threw it across the room, but as the area was well reddened, it was not replaced. I stayed with him until 2 a. m., at which time the bricks were removed, and the patient, with clothes sat-urated with steam and perspiration, left unchanged till

Returning next day, I found him resting quietly, free from pain, temperature reduced to ror F., pulse slower, the purgative had acted, and general condition satisfactory. In a well heated room his clothing was changed, the bed also, and he ate a little milk toast and soft cooked egg. Twenty-four hours later, his pulse showing decided softening and lessened size, the aconite and tartar emetic tablet was discontinued, and one of digitalis, nitroglycerin, and strychnine substituted. In seventy-two hours from the time he was taken sick his pulse and temperature were normal, his appetite good, his sleep natural, and he proceeded to uninterrupted recovery. He was advised to remain indoors a few days longer, and in a week he was back at work.

The most noteworthy point in the case was the tremendous rapidity with which the most severe symptoms developed from a condition of perfect health. emphasizing the fact, more forcibly than any other coming under my observation, that treatment if effectual in cutting short an attack—and I am convinced that in the great majority of cases pneumonia can be aborted—must begin early. In this case not only hours, but one might almost say minutes were valuable.

I know that some high authorities, Dr. Osler for instance, maintain that "pneumonia is a self limited disease, which can neither be aborted nor cut short by any known means at our command," but the

*Read before the Roanoke Verdeny of Medicine, April 20, 1938

proof of the pudding is in the eating, and in a series of cases numbering more than a dozen treated by this method, with one hundred per cent. of recoveries, cases ranging in age from six to seventy-two years (the last mentioned an old man treated thus in two attacks, with a two year interval), it would be asking too much to believe that the prompt recovery in every instance was a mere coincidence.

Now as to the rationale of the treatment. In the first place it is only of value in the stage of engorgement. In the histology of the lung we remember that the ultimate ramifications of the bronchi terminate in the infundibula, from which open the minute cæcal pouches, the air cells. A branch of the pulmonary artery accompanies each bronchus and bronchiole, without anastomosis until it reaches the walls of the air cell or alveolus, where it ends in a rich capillary network upon, or rather within, the walls of the air cell. In the beginning of the stage of engorgement these capillary vessels are greatly distended, the alveolar epithelium swollen, the air cells themselves containing serum and some blood corpuscles. Now, the rational thing to do is to endeavor to decongest these over filled bloodvessels. Formerly, and to some extent even at the present time, bleeding was advocated. But it is safer and easier to bleed the patient into his own veins; and none of the veins of the body lend themselves to this purpose more readily than those in the skin. We are told by physiologists that the skin is capable of containing in its bloodvessels at one time, one fourth of the entire volume of blood. This is Nature's provision for cooling the body, namely, dilating these bloodyessels, whence the heat is radiated to the surrounding air. If this is not enough she bathes the body in perspiration, and the rapid evaporation still further cools. So in thismethod, the patient is surrounded by heat—dry heat might do, but moist heat is better-which dilates the cutaneous vessels just as certainly, and as quickly, perhaps even more quickly and safely than drugs will do. At the same time the moist heat, by inducing greater amount of perspiration, promotes elimination of toxines through the skin.

To avoid a too sudden reaction, it is probably best to keep up the effect by mild medication. The combination which I mentioned meets the various indications as well as any-possibly beter than any other I know of. Aconite has many advocates. Bartholow says, "it gives good results"; Da Costa advises, "reduce the circulation by aconite"; Austin Flint remarks it "is an effectual sedative remedy"; Phillips writes, "it is valuable in the first stage"; Ringer asserts, "it has marked effect," etc., etc. Tartar emetic at one time had a great vogue, but is not now often employed. However, Bartholow admits "small doses may be useful, given with care"; Wilcox observes, "it increases the sweat, and produces a marked reduction of temperature"; Flint advises, "if the skin is hot and the pulse frequent, tartar emetic may be given as a sedative, but the dose should not be carried to the extent of producing marked nausea"; Potter advocates its use as "a very efficient agent, if used in small doses (one sixtieth to one fortieth grain) in acute inflammatory affections, especially pneumonia. As to ipecac. it is recommended by Wilcox as an agent which "decreases pulmonary congestion, and promotes diaphoresis"; Potter says, "it has been efficiently employed as an antihæmorrhagic," and "is considered very useful in coughs and acute catarrh." In regard to morphine, it allays the pain, increases the sweat. and gives the patient power to breathe, also it tranquillizes the circulation, controls the cough, and permits the patient to sleep. Dr. Osler advocates at the onset a quarter grain hypodermatically. Dr. Flint says, "opium may be given with propriety and advantage in the first stage in doses sufficient to relieve the pain and tranquillize the system." Personally I have never used a blister, and never felt the need to use one. I do use oil of turpentine, however, as a counterirritant almost to the point of blistering, and believe it a valuable item in the treat-

I have no quarrel with the open air treatment, but have never used it in pneumonia, though I advocate it in other affections of the respiratory organs, my patients have been treated often in very open cabins

Such in brief is the method I have adopted in the management of this disease which is slaying its thousands, and while my experience has not been extensive, and though Hippocrates says, "experience is fallacious," I offer it for what it is worth, and until a better method is shown I shall continue to use it, for I believe in its efficacy. I am partly indebted to an article by Dr. C. M. Miller for the suggestion in the beginning.

Correspondence.

LETTER FROM LONDON.

Las Cas ad de Lecture a Tuberculous Injection . Tuberculous Disease in Ireland .- The Water Supply .- Medi-Medical Teaching .- The Death of Sir John Banks.

The Cavendish Lecture was delivered this year by Sir William Whitla before the West London Medicochirurgical Society, and dealt with the very important problem of the mode of infection in tuberculosis. Sir William Whitla is senior physician to the Royal Victoria Hospital, and professor of materia medica in Queen's College, Belfast, where he has carried out a long series of experiments with Professor Symmers with the object of finding out the most likely channel of infection in pulmonary and other forms of tuberculosis. As a result of these experiments he reaches the conclusion that the intestinal route plays a far more important rôle in the production of human pulmonary tuberculosis than has been hitherto recognized. This teaching is, of course, strongly opposed to that of Professor Koch, who has always held that the lungs may be looked upon as the usual primary seat of tuberculous infection, and that in the majority of cases the bacilli find their way into the lungs with the inspired air. The comparative rarity of primary intestinal tuberculosis was one of the points adduced by Koch against the intestinal origin of pulmonary tuberculosis, and this fact has long served to divert attention from this question, but in the light of Sir William Whitla's experiments it is difficult to resist the conclusion that the alimentary canal plays a very important part in the production of pul-monary tuberculosis. The lecturer also discussed the question of the identity of human and bovine tuberculosis, and here again he differs with Koch in his conclusion that human and bovine tuberculosis are practically identical, that the tuberculosis of bovines is transmissible to man, and vice versa. Sir William emphasizes the importance of recognizing that the milk of tuberculous cows is a common source of tuberculosis in children through the channel of the alimentary canal, and in confirmation of this points to the fact that the bovine type of bacillus has been detected in a considerable percentage of cases of human tuberculosis. Sir William makes out a very good case for the intestinal origin of tuberculosis, one which should lead to

further investigation of this problem.

The question of tuberculosis in Ireland has also been occupying the attention of the present government. This disease is very common in Ireland. In England the death rate from this cause is 1.6 per 1,000; in Ireland it is 2.7, and a bill has been introduced into Parliament which aims at controlling its spread. The Tuberculosis Prevention (Ireland) Bill, 1908, was introduced by Mr. Birrell, the Irish Secretary, and has now passed the second reading and will shortly be dealt with by a committee of the House of Commons. Among the principal provisions are the compulsory notification of the disease in all stages, the inspection of milch cows by government officials, and the slaughtering of any cows found suffering from tuberculous disease of the udder. The bill also makes provision for the nursing of persons with tuberculosis in their own homes by trained nurses, and enables the local authorities to increase their hospital and sanatorium accommodation for tuberculous patients. The bill is certainly a step in the right direction, and its effects will be closely watched by every one concerned with the administrative control of tuberculosis.

A report issued by Dr. Houston, the director of water examinations, to the Metropolitan Water Board, emphasizes a most important advance that has been made in our knowledge of the best methods for purifying our water supply. It appears that organisms lose their vitality and very soon die in water that has been simply stored, so that by making use of storage tanks in which every drop of water could be stored for a certain time (somewhere about two months) before its distribution to the public it would be possible to reduce the likelihood of typhoid infection from this source to a minimum. Not only does simple storage kill the typhoid bacillus, but it also destroys the Bacillus coli. In times of extensive flood the water supplied to the public is not stored so long as during time of drought, and it has been found that the number of microbes present in samples of water during flood time is very much greater than at other seasons, a fact which strongly supports the observations of Dr. Houston. Further, the tables show that the incidence of typhoid fever in London is always greatest after exceptionally heavy floods, and in a table published some years ago by Sir Shirley

Murphy, medical officer of health to the County of London, the "curve of typhoid incidence" reached its highest point just after the Thames floods had attained their maximum. These observations, taken together, lead to conclusions of the greatest im-

portance to the public welfare.

A party of about eighty French medical men, representing the association known as the Voyages d'études médicales, has paid a visit to London, and during the course of a week visited all the great general hospitals as well as the French Hospital and the museum of the Royal College of Surgeons. At Guy's Hospital they were received by Dr. Newton Pitt and Mr. Arbuthnot Lane, and were much interested in a group of patients collected for their inspection upon whom Mr. Lane had performed total extirpation of the large intestine for constipation and toxæmia. The healthy appearance of these patients greatly impressed the visitors. At St. Bartholomew's Hospital they were received by Dr. Norman Moore, the senior physician, in the great hall. This hospital is famous in France for its nursing system, and is regarded as a model to be followed in the reform of nursing now going on in France. The party visited a medical and a surgical ward, and in each ward the duties of the nurses were carefully demonstrated. The orthopædic department was also visited, and a demonstration of the Swedish exercises was given.

A dinner was given in their honor at the Hotel Cecil, and a party of about 170 ladies and gentlemen assembled under the chairmanship of Dr. George Ogilvie. A feature of the after dinner speeches was that they were all in French. A capital musical entertainment brought the proceedings to a

close.

Some of the professors in the medical schools in making use of the cinematograph in lectures to students. This fact has been seized upon by the newspapers as sufficient for sensational reports relating to the cinematographing of patients during operations. Undoubtedly the cinematograph is a valuable improvement on mere pictures or photographs of diseased states, and it ought to be of special value in many nervous diseases. It is difficult to see any objection to its use for this purpose. The cinematograph picture of an operation would not be of any use as a means of teaching students when they had the opportunity of actually seeing or assisting at operations. The only surgeon who has had his operations cinematographed appears to be Dr. Doyen, of Paris, but his example has not been followed in England.

The death has occurred of Sir John Banks, physician in ordinary to the King in Ireland, at the age of ninety-five. He was born in London, and was educated in Trinity College, Dublin, where he obtained the degree of M. D. in 1843. He became president of the Royal College of Physicians of Ireland in 1869. He was for a time regius professor of physic in the University of Dublin, and was physician to several Dublin hospitals. He enjoyed a very large and extensive practice, and his opinions as an alienist were highly thought of. In 1868 he showed from legal evidence that in 1741 Dean Swift was found to be insane. Sir John was a

leader in the scientific and social circles of Dublin for a long time, and all the viceroys for the last fifty years have experienced his hospitality.

Therapeutical Aotes.

Somnifacient in Cardiac Insomnia.—In addition to the usual treatment the following potion is advised in *Journal de médecine de Paris* for June 20th:

Salol as a Bowel Antiseptic is best prescribed, according to the *Journal of the American Medical Association* for July 25, 1908, as follows:

The Use of Alkali Phosphate Waters in the Treatment of Digestive Disorders, and Particularly of Constipation.—Barrère (Bulletin général de therapeutique for June 8, 1908) observes that alkali phosphate waters are of real value in the treatment of affections of the digestive tract. He cites the following formula for a phosphatic water which is recommended by Professor Albert Robin in his work entitled Traité des maladies de l'estomac:

In his clinical lectures during the session of 1906 and 1907 Robin revived anew the same prescription. modified as follows:

This phosphated water is used to-day in the Beau-

jon Hospital

The foregoing is a formula very similar to that advised by Soupalt in his work entitled *Les dilatations de l'estomac*, containing the following proportions:

These waters are prescribed by Robin and Bardet in hyposthenic conditions, associated with gastric and intestinal fermentation and all forms of constipation, in doses of one half to one wineglassful, taken immediately on arising, one hour or a half an hour before breakfast or the midday meal, and occasionally three or four hours after dinner. Soupalt recommends his prescription to be taken once a day in wineglassful doses the first thing in the morning on an empty stomach.

NEW YORK, SATURDAY, AUGUST 15, 1908.

THE PUBLIC HOSPITALS OF NEW YORK.

More than two years and a half ago the mayor of New York appointed a commission to consider the whole subject of the public hospitals of the city and to devise "some comprehensive plan for the reorganization, extension, and administration of the public hospital system." The commission has now made its report, dated July 28, 1908. To a great extent the report deals with the ambulance service. That feature of our hospital work we have already commented on (see the *Journal*, July 11th, page 76).

The commission favors an extension of the lease of Ward's Island to the State for the uses and purposes of the Manhattan State Hospital-either a short extension, "say for five years, with the understanding that the property is to be surrendered to the city at the end of that period," or an extension for not less than fifty years, "with an agreement upon the part of the State that, in consideration of such lease, it will construct on Ward's Island a modern hospital for the insane, for the care of the insane poor of the city of New York, the plans to be approved by the Board of Estimate and Apportionment of the city of New York." The commission prefers the latter arrangement, and it was authorized by the last legislature, the new hospital to be constructed within ten years. The result promises to be beneficial to the insane of the city and favorable to the adequate teaching of psychiatry within the metropolis.

The present situation in the matter of caring for persons with tuberculous disease is regarded by the

commission as unsatisfactory, mainly on account of the divided control of the institutions which afford such care. Divided administration, indeed, seems to the commission undesirable as regards the public hospitals in general. The Department of Public Charities administers the City (Charity) Hospital, the Metropolitan Hospital, and the City Home Hospital, on Blackwell's Island; the New York City Children's Hospitals and Schools, on Randall's Island; the Kings County Hospital, the Cumberland Street Hospital, the Bradford Street Hospital, the City Home Hospital, and the Coney Island Hospital, in Brooklyn; and the Sea View Hospital, in the borough of Richmond. The Department of Health administers the Willard Parker Hospital, the Scarlet Fever Hospital, and the Reception Hospital, in the borough of Manhattan; the Riverside Hospital, at North Brother Island; the Kingston Avenue Hospital, in the borough of Brooklyn; and the Otisville Sanatorium, in Orange County. The Board of Trustees of Bellevue and Allied Hospitals administers Bellevue Hospital, the Gouverneur Hospital, and the Harlem Hospital, in the borough of Manhattan; and the Fordham Hospital, in the borough of the Bronx.

The commission thinks that all these hospitals should make provision for treating tuberculous patients, and that all of them should be under one jurisdiction, preferably that of a single commissioner. This would require a revision of the charter, and, while it would make the system of the city departments uniform, its adoption, it seems to us, ought to be very carefully considered. The present management of Bellevue and the allied hospitals is so satisfactory that we think it ought to be continued at least until the new Bellevue is in good working order. If a single department is to be charged with the administration of all the public hospitals of the city, it need not be a new one, but might properly, we should say, be the Department of Public Charities, for certain institutions that are not really hospitals can probably best be administered with the aid of special experience in hospital management.

The extension of hospital facilities, especially in the boroughs of Queens and the Bronx, where the population is growing rapidly, is justly urged by the commission, also more care in selecting sites for new hospitals in all the boroughs with a view to the needs of different localities. "The construction of the new Bellevue," says the report, "should be expedited as rapidly as practicable, and in the relatively near future a new general hospital, with capacity for several hundred beds, should be constructed on the middle west side of the city in the borough of Manhattan." Both these recommendations, we believe, will meet with general approval.

BENZOIC ACID AS A FOOD PRESERVA-TIVE.

There has recently been issued by the Bureau of Chemistry of the Department of Agriculture the fourth part of a report entitled Influence of Food Preservatives and Artificial Colors on Digestion and Health. It is a brochure of rather more than 250 pages, prepared by the chief of the bureau, Dr. Harvey W. Wiley, with the collaboration of several members of his staff. It deals with benzoic acid and the benzoates employed as preservatives. The investigations on which it is founded have been largely experimental, the so called "poison squad" having been made use of. Eighteen tables are given in this section of the report, which in its entirety constitutes Bulletin No. 84.

The general conclusion arrived at is that the continued ingestion of benzoic acid, either free or in combination in the form of sodium benzoate, "is highly objectionable and produces a very serious disturbance of the metabolic functions, attended with injury to digestion and health." As is the case with boric acid, salicylic acid, and sulphurous acid, the injurious effects include grave derangements of digestion, attended by phenomena indicative of irritation, such as nausea, headache, and in a few cases vomiting. In the experiments these results were observed in healthy individuals living on good and nourishing food and under proper sanitary conditions. It is argued, therefore, that the effects noted would be more pronounced and more enduring in weak persons or in those of impaired health.

It was observed that the subjects of the experiments lost flesh distinctly, and this fact is held to indicate either defective assimilation of food or increased recrementitious processes. It is declared that the influence of benzoic acid and sodium benzoate upon metabolism was in no instance of a favorable character; while the changes were in many cases not highly pronounced, they were always of an injurious nature. Nature's efforts to eliminate these substances, it is remarked, are corroborative of the deductions mentioned. By these efforts benzoic acid, so far as possible, is converted into hippuric acid and so excreted, but there is a tendency to retain benzoic acid and especially sodium benzoate in the system for a notable length of time. The injurious effects are more rapidly produced when benzoic acid is administered as such than when sodium benzoate is given, but eventually the deleterious action is the same; consequently the use of the benzoate as a preservative is really no more defensible than that of the uncombined acid.

In the interests of the public health, finally, both benzoic acid as such and sodium benzoate should be excluded from food products. It is evident that

our grandmothers knew their business when they made their pickles, their jams, and their preserves without any extraneous preservatives. If they used preservatives, they used them for their flavor and not with any theoretical notion of their antizymotic action. We honor the memory of the dear old dames, and we rejoice that their unsophisticated methods are justified by modern scientific investigations.

SERUM REACTIONS AND THE GAME LAWS.

When Uhlenhuth, Wassermann, and Schultze elaborated the precipitin tests for the identification of various bloods, a relatively final solution of the problem of the distinction of animal bloods was offered. Since 1901 blood tests by the methods outlined have been extensively used in medicolegal work, and in Continental countries, at least, such tests have been received with confidence by the courts and are now considered as established. That they have limitations is well known, but such limitations, being granted and allowed for, render the experimenter all the more secure in his conclusions. Specific sera exist for other tissues than blood, and, although a rich literature has sprung up relative to them, little of medicolegal significance has arisen save in the spinal cord fluid tests for syphilis, locomotor ataxia, and general paresis, and, on the Continent, isolated instances of tests undertaken to determine the character of certain animal tissues.

Dr. F. P. Gay, of the Pathological Laboratory of Harvard University, has given in the Journal of Medical Research for July an interesting account of the utilization of the musculoprecipitin test for the detection of violators of the Massachusetts game laws. During the Winter of 1907 the Fishery and Game Commission of Massachusetts became convinced that deer were being killed contrary to law. In February a woodchopper saw a suspect loading a sleigh with suspicious bundles, and the game warden later found unmistakable evidence of the killing and bleeding of a large animal. Running the tracks back led them to the house of the suspect, which, on being searched, was found to contain only the mutilated heart of a large animal. The suspect said it was the heart of a calf which he had purchased at the local market, but the statement could not be substantiated on inquiry at the market. The heart was turned over to Dr. Gay for examination, to determine if possible whether it was from a calf or from a deer.

Dr. Gay shows in his discussion of the problem that on *a priori* grounds the solution seemed unpromising, since other workers, notably Vallée and Nicholas, with European species of the *Cervida*,

had obtained very contradictory results; but Nuttall, in his study of the seroprecipitins, had found that, of seventeen species of the deer family studied, fourteen reacted more or less with an ox precipitating serum, although ox serum gave no reaction with antisera to the hog deer and the Mexican deer. In addition to the preparation of an extract from the suspected heart, Gay made extracts from venison as well, and ran both through the tests with extracts obtained from the hearts of a calf and a young cow. Rabbits were used for the test. The results obtained were very striking. The suspected heart and the venison behaved alike, and in every respect the direct opposite of the cow's heart and calf's heart. It was very evident that the suspected heart was from a deer and not from a calf. We infer from Dr. Gay's closing sentence that the malefactor was convicted on the evidence supplied by the serum reactions.

SCARLET FEVER AND THE VERMIFORM APPENDIX.

M. René Kauffmann (Thèse de Paris, 1908; Semaine médicale, July 8th) has made a number of interesting observations on the behavior of the vermiform appendix in connection with scarlet fever. The appendix has been called the "abdominal tonsil," and Kauffmann seems to regard the organ as analogous to the faucial tonsil in its reaction to the poison of scarlet fever and as essentially a lymphatic structure. If, he says, appendicular inflammation is not oftener observed in the course of the disease, it is partly because the abdomen is not as a rule subjected to methodical examination and partly because the inflammation generally remains latent. In the majority of instances it does not appear to be severe enough to give rise to spontaneous pain.

The initial vomiting, Kauffmann suggests, may not be altogether dependent on the pyrexia, and he thinks that in itself it ought to lead one to examine the abdomen carefully. Deep pressure in the right iliac fossa will evoke acute pain at McBurney's point unless the patient is so overwhelmed by the scarlatinal poison as to be profoundly prostrated. Scarlatinal inflammation of the appendix manifests itself also by pronounced intestinal derangement, either diarrhoza or, more commonly, obstinate constipation.

It is not solely in the pyrexial stage of scarlet fever that appendicular inflammation may declare itself; he has observed it four times during the per iod of desquamation and twice after the fifteenth day. The author knows of no practical conclusions to be drawn from this late appearance of the trouble in particular, he remarks, the influence of

diet appears to be very problematical. All forms of appendicular inflammation may be met with, but generally the only symptoms to be noted are slight and transient elevation of the temperature, pain at McBurney's point, and rigidity of the abdominal wall at that situation. Though a scarlatinal attack of inflammation of the appendix may be grave in itself, it is still more serious in consequence of the sequelæ to which it leaves the patient exposed; even when the lesions have subsided, he remains predisposed to subsequent outbreaks, and they are rendered additionally dangerous by the fact that a previously infected structure is involved.

In all instances of the post mortem examination of persons who have died of scarlet fever or of any of its complications Kauffmann has found special histological changes in the vermiform appendix. As regards its gross appearance, the organ is observed to be injected, with hemorrhagic points in its mucous membrane, and the glands of the mesoappendix are invariably engorged. Microscopically, the lesions are found to consist of infiltration of all the coats of the appendicular wall by multinuclear leucocytes and lymphocytes and considerable hypertrophy of the follicles, some of which have been converted into abscesses opening into the cavity of the appendix. The glands show a simple inflammatory reaction.

The treatment must be largely of a preventive character. Baths and purgatives, the author thinks, should be interdicted. In malignant cases cold applications should be made to the abdomen, and absolute abstinence from food or a strict milk diet enforced. In some instances a manifestly acute inflammation may render surgical intervention necessary, but only when medical treatment has proved inefficacious.

THE VOMITING OF PREGNANCY.

Dr. E. Schwarzenbach, of Zurich, has written an interesting essay on the ætiology and therapeutics of the vomiting of pregnancy, which appeared in the Correspondens-Blatt für schweizer Aerste for July 15th. The well known fact that this vomiting occurs especially in the morning led him, like others before him, to the conclusion that prolonged fasting was the chief exciting cause of the occurrence. The pregnant woman is afraid to eat because she fears that she will vomit. Thus is formed a vicious circle: The pregnant woman does not eat because she will vomit; she vomits because she does not cat. Our author, therefore, insists upon short intermissions between meals, even during the night, and states that he has observed good results from the plan. A great deal of persuasion is often necessary to induce a pregnant woman suffering with hyperemesis to eat; but when she has once tried to eat small quantities about every two hours, even during the night, she will soon adhere to this schedule, and it will greatly benefit her and soon relieve her entirely.

This theory is not a new one. We know that the vomiting of pregnancy is a physiological act, and therefore medication is not likely to be of much help. Dr. Schwarzenbach now puts forward tentatively an explanation of this vomiting. He helieves that even a light grade of hyperemesis gravidarum is a symptom of intoxication. A certain toxine of pregnancy, formed in the stomach, excites the mucous membrane of this organ, and thus induces vomiting. An empty stomach will react stronger, as the toxine is in concentrated form, while the contents of a full stomach dilute the toxine, which then cannot act so intensely. Washing out the stomach in the morning, after a prolonged suspension of eating, will therefore be of great help. The place of this lavage may be taken by the drinking of a cup of fluid upon awakening, which fluid -tea, milk, water, etc.-will be vomited, thus expelling the toxine. The author thinks that the principal element of treatment for hyperemesis gravidarum, besides rest in the recumbent posture, is frequent feeding.

Obituary.

GEORGE MICHAEL EDEBOHLS, M. D., of New York.

Dr. Edebohls died on Saturday, August 8th, at the age of fifty-four years. He was a native of New York and a graduate of the College of Physicians and Surgeons, of the class of 1875. He early achieved prominence as a surgeon, especially in abdominal and gynæcological work. He was officially connected with several hospitals and was a member of the faculty of the New York Postgraduate Medical School and Hospital. He was widely known for his advocacy of the operation of decapsulation of the kidney as a remedy for Bright's disease. He died at the height of his powers, esteemed and liked by his professional brethren and by all who knew him, for he was an upright and attractive man.

Rews Items.

Personal.—Dr. William Peacock, of Philadelphia, has been appointed district physician to the Bureau of Health.
Dr. Thomas C. Gifford, of Trenton, will remove to Utica, New York, where he will resume his practice.

Bunsen Monument.—The monument in honor of Robert Bunsea, designed by Professor Volz, of Karlsruhe, Baden, was unrealed at Heidelberg on August 1st.

Medical Congress Opens.—The fifth Pan-American Medical Congress was inaugurated at Guatemala City on August 6th. All of the nations of the New World are represented, a great many distinguished physicians being among those present.

Cortland County Medical Society to Observe Hundredth Anniversary.—In commemoration of the hundredth anniversary of the founding of the society in Homer, N. Y., a centennial meeting was held at the Congregational Church of Homer on August 5th, at 10 o'clock in the morning. Many prominent physicians from out of town were present.

Samuel D. Gross Prize.—The Philadelphia Academy of Surgery has announced that essays in competition for the Samuel D. Gross prize of \$1,500 will be received until January 1, 1910. The candidate must be an American citizen; the prize is awarded every five years to the writer of the best original essay, not exceeding in length one hundred and fifty printed octavo pages, and illustrating some subject in surgical pathology or surgical practice, founded upon original investigation.

The Health of Pittsburgh.—During the week ending August 1, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Chickenpox, 2 cases, 0 deaths; typhoid fever, 20 cases, 1 death; scarlet fever, 9 cases, 0 deaths; diphtheria, 9 cases, 2 deaths; measles, 37 cases, 4 deaths; whooping cough, 16 cases, 0 deaths; pulmonary tuberculosis, 13 cases, 10 deaths. The total deaths for the week numbered 143 in an estimated population of 565,000, corresponding to an annual death rate of 13.10 per 1,000 population

Convalescent Camp at the Binghamton, New York, State Hospital.—Dr. Charles G. Wagner, Superintendent of the Binghamton, New York, State Hospital for the Insane, has formed a convalescent camp on the hospital grounds, which is designated as a part of the treatment of convalescent patients. The camp consists of five tents and a small frame structure used as a kitchen, and is connected by telephone with the main hospital. The dining tent seats twenty-five patients. Hammocks, swings, settees, boats, music, and a library of reading matter complete the camp equipment.

First Aid in Railway Accidents.—Reports from the Pennsylvania Railroad show that since January I, 1008, four thousand two hundred employees of the Western Pennsylvania Division of the Pennsylvania Railroad system, terminating in the Pittsburgh district, have received instructions how to render first aid to the injured. About twelve lectures are field each month and the instructions are given by the redical examiners. Employees are taught how to place injured passengers on stretchers and how to carry them; how to bind up wounds and fractures; how to treat burns, etc., until competent medical aid can be obtained.

Day Camp for Tuberculous Patients.—The New York Comby Red Cross Society in its crusade against tuberculous will open a day camp for tuberculous patients on the roof of the Vanderbilt Clinic at Sixtieth Street and Amstersterdam Avenue on October 1st. The expenses, estimated at \$5,000, to defray the cost of nursing and nourishing the patients, will be raised by voluntary contribution. The plan is to care for at least forty patients all of the year, and the camp will be open at first only in the day time. The idea of a day camp was first tried by the Charity Organization of New York on the old ferryboat Southfield, after the City of New York had purchased the Staten Island ferry line.

Infectious Diseases in New York:

We are indebted to the Bureau of Records of the Department of Health for the f downing statement of new cases and deaths reported for the two weeks ending August N. 1508.

The Health of Philadelphia.—During the week ending August 1, 1008, the following cases of transmissible diseases were reported to the Bureau of Health: Typhoid fever, 43

cases, 3 deaths; scarlet fever, 20 cases, o deaths; chickenpox, 2 cases, o deaths; diphtheria, 42 cases, 3 deaths; cerebrospinal meningitis, 3 cases, 3 deaths; measles, 4 cases, 1 death; whooping cough, 31 cases, 10 deaths; plumonary tuberculosis, 148 cases, 53 deaths; pneumonia, 30 cases, 21 tuberculosis, 148 cases, 53 deaths; pneumonia, 30 cases, 21 deaths; erysipelas, I case, I death; puerperal fever, I case, 3 deaths; cancer, II cases, 14 deaths; tetanus, 5 cases, 1 death. The following deaths were reported from other transmissible diseases: Tuberculosis, other than tuberculosis of the lungs, 7; diarrhea and enteritis, under two years of age, 92; dysentery, I. The total deaths numbered 473 in a population of 1,532,738, corresponding to an annual mentality of 1600 per 1,000 population. The total infant mortality was 188; under one year of age, 154; between one and two years of age, 34. There were 35 still births, 17 males and 18 females. The total precipitation was 0.03 inch. The temperatures were high. There were 4 deaths from heat and sunstroke, 3 adults and 1 minor.

Charitable Bequests.—By the will of Mrs. Annie L. Lowry the following bequests were made: The Industrial Home for Blind Women, \$20,000; Philadelphia Home for Incurables, \$10,000; Pennsylvania Society to Protect Children from Cruelty, \$13,000; Home of the Merciful Savior dren from Cruelty, \$13,000; Home of the Merchill Savior for Crippled Children, \$10,000; House of the Holy Child, \$5,000; Association for the Care of Colored Children, \$5,000; Home for Infants, \$5,000; Presbyterian Hospital, for the Mary L. Davidson free bed, \$5,000; German Hospital, for the Nathan Davidson free bed, \$5,000; Philadelphi, The Carlon free bed, \$5,000; Philadelphi, The pital, for the Nathan Davidson free bed, \$5,000; Philadelphia Home for Incurables, for the Sarah K. Davidson free bed, \$5,000; West Philadelphia Hospital for Women, for a free bed, \$5,000; Pennsylvania Retreat for Blind Mutes and Aged and Infirm Blind Persons, \$5,000; Old Men's Home, \$2,500; Western Home for Poor Children, \$2,000; Home for Aged and Infirm Colored Persons, \$5,000; Children's Seaside House, Atlantic City, \$5,000; Friend's Asylum for the Insane, Frankford, \$3,000; Pennsylvania Hospital for the Insane, to be used for poor women patients, \$3,000; Pennsylvania Training School for Feeble Minded Children, Elwyn, Pa. \$3,000; Ada Lee Orphanage, Calcutta, India, \$3,000.

University Notes.—Dr. Henry R. Alburger, of the University of Pennsylvania, has accepted a call to the University of Indiana, as professor of pathology.-Dr. J. Edwin Sweet, who has had charge of the Laboratory of Experimental Surgery of the University of Pennsylvania for two years, has been advanced to the grade of assistant professor.—By the death of William Davis Ely, '36, Yale College, the title of the oldest living graduate of Yale falls to Dr. Gurdon Wadsworth Russell, who graduated from the Medical School in 1837.—Dr. H. T. Marshall, formerly professor of nathology in the Philippine Medical School, has been elected professor of pathology in the University of Virginia Medical School.—Dr. J. A. E. Eyster, associate professor of physiology at Johns Hopkins University, has been elected professor of pharmacology and materia medica.—Dr. Carl Meloy, formerly instructor at Johns Hopkins in pathology, has been elected adjunct professor of pathology.—Dr. C. W. G. Rohrer has been appointed associate professor of pathology and assistant in genito-urinary diseases at the College of Physicians and Surgeons, Baltimore.——Foreign.—Dr. Aron, of Berlin, has accepted the position of professor of physiology in the Philippine Medical School.—Dr. H. Dold, of Tübingen, has been appointed lecturer in bacteriology and comparative anatomy in the Royal Institution of Public Health, London.—Dr. Steyrer, of the University of Berlin, has received the title of professor.—Professor Lüthje has been called to the University of Kiel as successor to Professor Quincke.—Dr. August Gürber, of the University of Marburg, as successor to Professor Heffter, to fill the chair of pharmacology.—Professor Nagel, of Berlin, has been called to the University of Kiel as been called to the University of Heiner, to fill the chair of pharmacology.—Professor Nagel, of Berlin, has been called to the University of Edinburgh.—Dr. George Joachimsthal has been appointed extraordinary professor of orthopædic surgery and director of the University Clinic at Berlin, which posts were vacated half a year, ago by the sudden Experimental Surgery of the University of Pennsylvania for two years, has been advanced to the grade of assistant has been appointed extraordinary professor of orthopacines surgery and director of the University Clinic at Berlin, which posts were vacated half a year ago by the sudden death of Professor Hoffa.—Professor Karl von Than, pro-fessor of medical chemistry in the University of Budapest, Hungary, died at the age of seventy-four years.

- Some Aspects of Gonorrhea (Shattuck Lecture),
 By Frederick Forchheimer.
 Stenosis of the Pylorus in Infancy. A Surgical Emergency. A Report of Four Cases Operated on with Recovery. End Results. By CHARLES L. SCUDDER.
- The Tonsils and Their Relation to the General Health,

 By CHARLES P. SYLVESTER.

 The Demonstration of the Spirochæla Pallida by the Method of Dark Field Illumination,
 - By WILLIAM C. QUINBY.

1. Some Aspects of Gonorrhœa.—Forchheimer, in the Shattuck Lecture, gives as results of his studies the following brief statements: I. The morbidity of gonorrhœa is diminishing. 2. The American army and navy are exceptions to this rule. 3. The present mathematical methods of deducing incidence of gonorrhea in all men from morbidity lead to fallacious results. 4. 54.1 per cent. of all males have gonorrhea during their lifetime. 5. We have not sufficient knowledge of the facts to state how many women have had gonorrhea during their lifetime. 6. The small number of his cases of sterility does not justify any positive conclusion. 7. Prevention of conception is the cause of "one child sterility" in the majority of instances. The object of his investigations was to determine the truth of the statements which have been made, in this country as well as abroad, by men and women who are interested in the suppression of venereal diseases. Whenever his figures have shown anything it is always that the propagandists have greatly overestimated the frequency, the complications, and the dangers of gonorrhea. This has been notably the case with specialists in genitourinary diseases in the male and in the female. With few exceptions, these observers have done that which is natural to all of us-magnified their office. Moreover, many who have written have been satisfied with the old figures of Ricord (eighty per cent. of all males have had gonorrhea), which, combined with the views of Nöggerath, would make it appear that very few men and women could escape having gonorihea. If to this there are added the remarkable mathematical gyrations of Blaschko, which are supposed to represent statistical methods, it is little wonder that the layman becomes an antigonorrhæic howling dervish. This is seen especially in Germany, according to Erb, where the women suffragists speak of an almost universal "poisoned wedlock" due to gonorrhœa, because no man enters matrimony healthy and pure, and his wife must suffer for the sins of his youth; of sterility increased and, therefore, countries depopulated. That there is much damage done by gonorrhea is abundantly shown by all statistics; therefore, it is a righteous cause to fight for its reduction. But no righteous cause is aided by such lurid statements as have been made in connection with gonorrhea. Eventually the truth will be found, and the good cause will suffer because of exaggeration. The harm done by gonorrhea is sufficient, even upon sober and sound investigation, to stimulate all of us to the necessity of combating the spread of venereal diseases. That they can be eradicated seems out of the question; that their frequency can

be reduced has been abundantly shown.

2. Stenosis of the Pylorus in Infancy.—Scudder observes that the prognosis is apparently hopeless, at least very grave, in cases treated medically. No case is on record which has received medical treatment and has recovered, in which it has been proved that the disease existed. One case only, that of Batten, was treated medically and, dying subsequently of some other lesion, was found to have a partial stenosis. Many cases are treated medically and come to operation, and the disease is found. The mortality following operation is bound to be always rather high, for the operation is done upon a weak child and the situation is that of an emergency. In the series of sixty operations studied by Scudder and Quinby, in 1905, the mortality from all operations was found to be 46.6 per cent.; in the 135 operations up to 1908 the mortality was found to be 48.8 per cent. The estimated medical mortality of these cases of pyloric tumor is between eighty and ninety per cent.

4. The Demonstration of the Spirochæta Pallida by the Method of Dark Field Illumination.—
Quinby says that it should be a routine practice to examine all suspicious lesions for the Spirochæta pallida. The organism has a definite morphology and can be distinguished from other spirochætae by careful microscopical examination. This is best done by the method of dark field illumination, with or without subsequent examination of a stained specimen. Since the organisms are not always numerous on the surface of the lesion, the method of obtaining them is of importance. A most satisfactory way is that of suction, and the case should not be pronounced negative until some such method has

been used.

The Treatment of Some Forms of Lens Displacement
Other than Those of Traumatic Origin.

By L. D. Brose.

1. A New Method of External Frontal Sinus
Operation without Deformity.—Beck, of Chicago, describes the technique as follows: An inci-

sion is made through the skin and subcutaneous connective tissue, through the upper margins of the eyebrows, then downward and inward as far as is usually done in the Killian operation. These two incisions are then joined by means of a transverse incision across the bridge of the nose. This skin and subcutaneous flap is then dissected upward until the upper limits of the frontal sinuses are exposed. This is determined by having a celluloid tracing of the radiogram. If the sinuses extend very high up on the forehead, then it may become necessary to make two small perpendicular incisions at the extreme limits of the flap (external canti). Place a celluloid tracing of the radiogram over the frontal sinus regions, and incise the periosteum all around the upper and lateral margins of the same, but not over the supraorbital borders or at the root of the nose. With a flat chisel the external table of the frontal sinus is then penetrated along the whole course of the above described incision through the periosteum, also severing the attachment of the sæptum of the frontal sinus from the posterior surface of the external table. This osteoperiosteal flap is then slightly pried open by means of a chisel, and a Gigli saw is brought down to the base of the frontal sinus, in other words, across the supraorbital margins. Carefully drawing the saw from within outward a few strokes will sever the bone but not the periosteum. Great care must be taken not to cut through this structure, rather not to saw through the entire thickness of bone, as it will readily break when it is everted downward over the nose. The skin flap is now reflected upward and the periosteal bone flap downward, thus exposing both frontal sinuses. If only one sinus is to be exposed, then the technique varies only in the osteoperiosteal flap, making the incision within the limits of the frontal sinus sæptum. The skin flap may be made by making a perpendicular incision from the internal angle of the orbit as high as the radiogram indicates the height of the frontal sinus, within the natural intersuperciliary furrow (wrinkle). Thoroughly eradicate the diseased mucous membrane, but do not curette, and enlarge the natural opening into the nose, using the Halle trephine or Good rasp. Also thoroughly remove the most anterior ethmoidal cells. Introduce a large rubber tube through which is passed a wick. This wicking is loosely folded within the cavity of the frontal sinus. The other end of the tube is passed down into the nose close to the floor, with a small portion of the wicking protruding. Replace the osteoplastic flap with its firm hinge to prevent falling in, and its natural upper marginal bevel where the anterior and posterior tables join. Bring down the skin flap and suture with silkworm gut, using the Halstead subdermal suture and a few horsehairs right over the bridge of the nose. The after treatment is to remove the gauze the next day, and on the third to the fifth day the rubber tube is replaced by a silver filigree or gold tube. In one case he used no tube, and now, four months since operation, the opening is sufficiently large to permit ventilation and drainage, and the patient is well. One should avoid the use of douches or the strong blowing of the nose immediately after operation.

4. A Special Diagnostic Phenomenon in Cerebellar Diseases.—Gordon reports six cases, four

of which came to autopsy. These four cases are conclusive as to the relation of the attitude of the head to a cerebellar disease. In the two purely clinical cases the symptoms of the cerebellar tumors were so typical that there was no doubt as to the diagnosis. In all six of the cases the head assumed a certain persistent position. In four cases it was turned to the side opposite the lesion during the entire course. In two of them it was inclined at first toward the seat of the lesion, but some time before the patients died the head changed its position. All the six cases are a good illustration of the fact that in cerebellar diseases, generally speaking, a special attitude of the head is a pathognomonic sign. Special emphasis is needed in regard to the increase of vertigo and headache when the inclined heads are turned forcibly toward the side of the lesion. This observation is quite novel. This peculiar change of position of the head during the evolution of the cerebellar syndrome did not occur in each of his cases at the same period of the disease. In the first case it occurred six months before death; in the fifth only three weeks before the fatal issue. In the third, fourth, and fifth cases the head assumed from the beginning the abnormal position with increase of vertigo and headache on turning it to the side of the lesion. In the second case the fixed position of the head on the side opposite to the lesion appeared after the severe symptoms set in. It is impossible to say why the change of position of the head occurs at various periods in various cases. It is also difficult to say why the change occurs at all and why, when the head is turned toward the lesion, the vertigo and headache become intolerable. At all events, it is useful, in his opinion, to retain this fact, that in his cases at least the increase of vertigo caused by placing the head in an opposite position was an indication for the seat of the cerebellar tumor. The number of his cases is certainly too small to draw definite conclusions.

9. Sodium Chloride in Blood.-Vanderhoof observes that the sodium chloride content of the blood and body fluids may be accurately estimated by an adaptation of Volhard's method of quantitative chloride determination after first precipitating and oxidizing the albumin bodies by nitric acid. method requires one cubic centimetre of blood, aspirated from a vein, and accurately measured in a volumetric pipette. Clinical applications of this method show a practically constant value for sodium chloride in a variety of conditions such as nephritis with and without cedema, uræmia, pneumonia, epilepsy, gastric anacidity, and conditions of cachexia. Variations in the amount of sodium chloride depend on the relative proportion of plasma and corpuscular elements in the specimen examined, with the highest values in cases of anæmia and the lowest figures in patients with venous stasis due to heart, kidney, or lung affections. The proportion of sodium chloride in the plasma of the blood is constant in conditions of health and disease.

12. A Comparative Study of the Dosage and Effects of Chloral Hydrate, Isopral, and Bromural on Cats. Sollmany and Hatcher have experimented on cats, the drugs being administered by the tormely time. They round that the effects of these times to can be dry ded into a limited number of

fairly well defined stages, but no criteria were found by which to distinguish the gradations of the effects within each stage. A fairly large range of doses, therefore, produces apparently identical effects; there are. furthermore, considerable variations in the individual reactions of different animals. A fair comparison between different hypnotics can, therefore, be made only on the basis of the averages of a considerable number of experiments, or by trying the several drugs on the same animal. The determination of the true "minimal hypnotic dose" of a drug is impossible, at least on cats. The smallest doses which produce effects sufficiently definite to serve as criteria, are relatively much larger than the doses which would be used therapeutically to induce sleep. If the dose of chloral required to produce a given effect is taken as 100, that of isopral would be about 60 (as stated by Hatcher) and that of bromural about 100. The bromural narcosis is, however, less profound. These ratios hold for all doses, small and large. The toxic quotient of the three drugs is about the same. The contrary conclusion of Impens is based on highly exceptional results. In practice, however, chloral is only half as dangerous as is isopral since excessive doses are generally expelled by vomiting, and since the subsequent very dangerous cachexia is less pronounced. On the other hand, relatively small doses of chloral do at times cause sudden death, namely when there is great excitement. Large doses of bromural are nearly equally as dangerous as corresponding doses of chloral, so that it cannot be called absolutely harmless. Since it is only advised, however, for the mildest cases, the temptation to give large doses would be absent. The hypnotic and motor effects of therapeutical doses of isopral and bromural set in and pass off much more quickly than those of chloral. The difference grows less pronounced as the dose is increased. The cachexia after large doses is considerably more profound and lasting after isopral than after the other drugs.

MEDICAL RECORD

2. Symptomatology of Recurrent and Abductor Paralysis of the Larynx.— Rice states that it is difficult to tabulate any statement of symptoms of the motor neuroses of the larynx, which renders the diagnosis positive without a careful examination with the laryngeal mirror. So far as the voice is affected, there is present every degree of impairment, from slight hoarseness to complete aphonia; a lesion which shows no abnormality in quiet conversation, would be apparent if the patient endeavored to use the voice in a forcible way, or tried to sing. The quality of the voice may even change from day to day, because the compensatory aid given by the unaffected muscles constantly varies in efficiency. In unduteral conditions, it may be stated

as a rule, that the voice shows a gradual and permanent improvement if the vocal cord muscles proper, the internal tensors on the affected side, retain their integrity; but if loss of power here allows the margin of the band to remain concave, there is little hope of vocal improvement. This is an important point in considering the prognosis of voice behavior. A careful study of the conversational pitch from day to day would show whether the impaired muscles were improving in tone. One unaffected lateral muscle can make approximation sufficiently good for ordinary conversation, provided the margin of the affected band is straight and not concave. We do not see so many concave bands, even in unilateral recurrent paralysis, because the author thinks the anterior muscle is, as a rule, not involved, and so the margin of the band is kept fairly straight and taut. As to dyspnœa. there are many degrees of this. If the loss of power develops slowly, and consequently if the respiratory space is but gradually narrowed, the patient accommodates himself, in a remarkable manner, to a iarynx almost entirely closed, without showing visible distress. Other symptoms such as vocal fatigue, laryngeal cramps, and cough, depend much upon the individual case and upon conditions apart from the neurosis. There are many cases where it will require numerous and most painstaking examinations to determine what muscle or group of muscles are at fault, because perhaps the state of partial paralysis will be masked by a condition of jerky spasm. A weak solution of cocaine sometimes aids, by quieting spasm, and by emphasizing the image of real loss of power. The symptoms of no two cases seem to be exactly similar, and it is most interesting to carefully study the behavior of each.

3. Mechanical Vibration in the Treatment of Constipation and Pelvic Conditions,-Snow states that the following principles should govern the application of mechanical vibration: 1. The vibration should possess the necessary rapidity and length of stroke demanded to meet a given condition, and exerted pressure must be such as to be painless. 2. The rapidity, stroke, pressure, or nonpressure should be governed by the indications and the patient's reactionary resistance. 3. The interruptions, when using interrupted vibration, should be limited in number to avoid exhaustion in nerve power. 4. The intervals of rest should be three, or even four, times as long as the period of impulse contact to assist in perpetuity and fixedness of the effect. 5. The periods of contact and rest should be rhythmical in the administration of interrupted vibration. 6, Vibratory effects should be applied to aid or promote functional activity of a part without altering the integrity or unfavorably affecting the normal activity of the part. Mechanical vibration in conjunction with dietary measures, and in some instances exercises directed to the compression of the bowels and liver. is the treatment par excellence for constipation. When carefully administered it is absolutely painless, harmless, and productive of the most gratifying results, and consequently, like many other physical measures, is worthy of a trial by the general practitioner. The quantity, kind, and quality of the food ingested must be regulated, in order that the functions may not be overtaxed, and that the food

may at the same time be nutritious and not too con-

COXA Valga.

The Removal of Lymph Glands,
On the Action of Chloroform Administered by Different Channels, By D. N. Paton and D. E. Lindsay,
A Note on the Administration of Ether by the Open
Method,
On Restal Decider

Rectal Drainage in Cases of Due to Appendicitis, By B. POLLARD.

I. Coxa Valga.—Tubby states that practically coxa valga is an opening out of the angle made by the head and neck of the femur with the shaft. The cases may be classified as follows: A. Congenital. (a) Associated with congenital dislocation of the hip. (b) Existing sui generis. B. Acquired. (1) Coxa valga arising from traction exerted by a pendent limb. This condition is met with in cases of marked infantile paralysis and also when the limb has been inactive over a long period. Coxa valga also occurs in the stump after amputation through the thigh in early childhood where the stump is pendent. (2) Static or functional varieties. When the centre of gravity of the trunk of the body is disturbed, as in scoliosis, the femur will be subjected to different conditions of stress and strain, due to unequal loading. For example, genu valgum on one side is associated with coxa vara on one side and coxa valga on the other. When a patient is partially paralyzed in one lower extremity, he leans on it, and the pelvis is tilted downwards on that side. The affected limb is therefore abducted, and coxa valga results. (3) Traumatic coxa valga arises after fracture of the neck of the femur, with impaction and malunion, and after injuries and separation of the epiphysis. A direct tail or blow on the trochanter can produce the lesion. (4) Coxa valga associated with rickets or other processes of bony softening, such as osteomyelitis and tubercle. As a primary affection rachitic coxa valga is almost inconceivable. (5) Idiopathic. Considerable doubt must be expressed as to the existence of this form. The cardinal symptoms and signs are abduction of one or both lower extremities, associated with external rotation and limitation of adduction. I. Pain and spasm of the abductor muscles are often seen at the onset of the trouble. 2. Gait. In a unilateral case there is limping and the trunk is inclined toward the affected side. In bilateral cases the gait is rolling and unsteady. This is due to the fact that the head of the femur is not wholly and firmly planted in the acetabulum. In some cases a partial subluxation occurs in walking. 3. Lengthening of the limb to the extent of two or three centimetres occurs in a unilateral case, and tilting up of the pelvis on that side does not compensate for the increased length. 4. The limb is abducted and rotated outward, while movements of adduction and inward rotation are limited. This is said to be pathognomonic. 5. In bilateral cases the patient stands on one leg with difficulty. In unilateral cases, when the patient stands on the affected limb the body is inclined toward the affected side. 6. Compensatory changes occur in the trunk. In unilateral cases the upper part of the body is inclined toward the affect-

convexity toward the affected limb. Sometimes the pelvis is twisted, so that the anterior superior spine on the affected side is below and in front of its fellow. 7. The region over the great trochanter is often flattened. This is in marked contrast to the prominence in congenital dislocation. In coxa valga the trochanter is often below Nélaton's line, and its outer surface looks somewhat backward. Some torsion of the neck upon itself may also exist. 8. The last word rests with careful skiagraphy, which often throws out cases which would otherwise be classed as coxa valga. The chief cause of error in diagnosis is confounding an incipient tuberculous coxitis with coxa valga. But in the latter condition upward tilting of the pelvis does not compensate for the lengthening of the limb. As regards treatment the writer gives preference to Galeazzi's method which consists in performing a linear osteotomy well outside the joint, and at the base of the neck. In all anomalies of direction of the neck this is the proper site of operation, and not the subtrochanteric region. If the section is made at the spot indicated, the pull of the great muscular masses, whose tendons are inserted into the great trochanter, is to drag the shaft of the femur upwards and lessen the angle of inclination. This upward movement of the trochanter should be followed step by step, by means of x ray photographs, and stopped at the proper moment by means of a firm plaster of Paris spica. In some cases operation can be dispensed with by the use of a high sole on the sound side, which will not only improve the gait, but will lessen the angle of inclination by changing the direction of weight pres-

Removal of Lymph Glands.—Parker's paper is based on a series of 430 extirpations of lymph glands, a few lymphadenomatous, but mostly tuberculous. He also reports in detail a formidable case in which the right jugular, subclavian, and innominate veins had to be, and were successfully tied. Lymphadenoma is not always rapidly fatal, as shown by the excellent results obtained in two cases. Operation certainly appears sometimes justifiable, or at least, temporarily justified by the event. But most of the cases, except those extremely rare ones which are benefited by arsenic given internally, die unrelieved. Frequently the removal is impracticable with any hope of safety, on account of the number, extent, and matting together of the growths, and the dangerous hæmorrhage, to say nothing of the difficulty

3. The Action of Chloroform.—Paton and Lindsay report the results of their investigations undertaken to throw light upon the ætiology of "late" chloroform poisoning, by a study of the changes produced in the protein metabolism of the body, with more special reference to any interference with the hepatic metabolism. Chloroform was given to dogs by inhalation, by the stomach, and hypodermically. They found inhalation of chloroform to produce little effect on metabolism, but the other two methods apparently had a depressant effect. They attribute these different effects, not to difference in dose but to the rapid climination of the chloroform after inhalation, and to its slow elimination after the other two modes of administration.

was given by the stomach than when it was given hypodermically: this was probably merely a question of dose, 50 c.c. being given in the one case, as against 10 c.c. in the other.

9. The Individual Plasma, to. Latah and Crime, By W. F. FLETCHER.

3. Examination of Gastric Contents.-Willcox discusses the importance and significance of the various chemical examinations of the stomach con-Before the test meal is given the patient should be kept on light diet for three or four days, and no drugs given. The meal, which should consist of a pint of very weak China tea with milk and sugar, and a round of thin buttered toast, should be given in the morning before food is taken, and removed one hour later. The dextrin in the toast acts as an efficient stimulus to the gastric glands; another advantage of this meal is that very little proteid or nitrogenous bases are present, and therefore much of the hydrochloric acid secreted by the stomach is present in a "free" state. This gives every opportunity, in a case of cancer, for free hydrochloric acid to be present. The gastric contents should always be drawn off without dilution; when the stomach is normal in size and there is no obstruction, from three to four ounces should be obtained. In cancer and mucous gastritis the contents are slimy and filter badly. The total acidity should always be estimated, but too much importance should not be attached to the result. In cancer the acidity is usually low, but it may be high from the presence of an excess of organic acids. Hydrochloric acid may be present as free acid; as combined with proteid and organic bases (when it is physiologically active); and combined with inorganic bases (physiologically inactive). The most trustworthy test for free hydrochloric acid is Gunzberg's, but too much importance must not be attached to its presence or absence, as it is physiologically of no more importance than hydrochloric acid combined with proteid and nitrogenous bases. In gastric cancer free hydrochloric acid is scarcely ever present, because as fast as it is secreted it combines with the mucin present. Free hydrochloric acid is rarely found in children, because milk is used for the test meal. Active hydrochloric acid ("free" + combined with organic bases) is the most important estimation in gastric chemical analysis. The author uses a modification

of Volhard's method of estimating chlorides. It is probably not true that the amount of hydrochloric acid in the gastric contents is lessened or absent when there is cancer elsewhere than the stomach, but not in the stomach. The presence or absence of lactic acid is of no great importance. The various organic acids are present in considerable amounts in cancer of the stomach and other conditions where much bacterial fermentation is going on in the organ. Mucin is usually present in cancer, and absent in ulcer and hyperchlorhydria. Sulphocyanides should be tested for, as when present with mucin they indicate that the mucin may come from the saliva. Estimation of the ferment activity is of the greatest importance, and the writer has devised a new method, based on the fact that the amount of rennin present in the gastric contents usually is proportionate to that of the pepsin.

4. Motor Functions of the Stomach after Gastroenterostomy.—Gray's conclusions, based on the use of bismuth and x ray method of investigation, are as follows: I. The stomach is, naturally, not of the usually accepted shape. 2. It is an organ of two compartments, cardiac and pyloric, the division between these being a physiological sphincter. 3. These two compartments act in great part independently. 4. During digestion the cardiac portion maintains to a great extent its saccular form, its distal part only being affected by visible peristalsis, while the pyloric portion is tubular and affected by strong peristaltic waves along its whole extent. 5. In order to maintain or restore physiological conditions as far as possible the stoma in the operation of gastroenterostomy should be made in the pyloric tube. 6. It is very doubtful whether food prefers to pass through the pylorus rather than through the lateral stoma some time after gastroenterostomy has been done in cases where there is no actual obstruction of the pylorus.

5. Intermittent Claudication.—Bramwell states that intermittent claudication or intermittent limping is a rare condition, and is due to temporary ischæmia of the affected parts. The essential clinical characteristics of the condition are: 1. Absence of symptoms when the parts are at rest. 2. The development of symptoms (painful limping, etc.) after exertion. 3. The disappearance of the symptoms after rest. 4. Absence of pulsation in the pedal arteries. Three factors seem to take part in the production of the ischæmia, (a) vascular obstruction; (b) vasomotor spasm; and (c) the increased demand upon the circulation of the part which muscular exertion entails. Intermittent claudication and the obliterative arteritis with which it is usually associated are more common in men than in women, and seem to affect Jews much more than the other races of mankind. In syphilitic cases mercury does good. It may be necessary to give morphine for the severe pain.

Semeiological Value of the Jugal and Commissional Semeiological Value of the Jugar and Value Leucoplasiae Called "Plaques des Funneurs."

By Professor L. LANDOUZY
Some Infectious Ulcers of the Fingers,
By LOUS QUELY A

Tuberculosis of the Pharyux.

1. Jugal and Commissural Leucoplasiæ.-Lan douzy asserts that buccal leucoplasiæ of various degrees are much more common than is supposed, that the use of tobacco is one of the best excitants for the production of the white plaques of stomatitis, but is in no way indispensable. The indispensable cause he believes to be the presence of syphilis.

2. Infectious Ulcers of the Fingers.—Queyrat describes with illustrations chancres, chancroids, and acute tuberculous ulcers of the fingers. The study of the acute tuberculous ulcerations of the fingers the author considers very important because their

diagnosis is often very difficult.

3. Tuberculosis of the Pharynx.-Letulle alleges that primary tuberculosis of the pharynx is clinically very exceptional, while secondary tuberculosis is much more common than was formerly thought. The lesions of tuberculosis of the pharyngeal mucous membrane give rise to various symp-

1. Chyluria.- Lüdke reports a case of chyluria the cause of which he ascribes to a preceding cholecystitis.

2. The Ophthalmoreaction.—Fehsenfeld considers that, while the ophthalmoreaction has value as a specific diagnostic remedy, it has no absolute significance when taken by itself.

3. The Conjunctival Reaction in Genital Tuberculosis.—Hörrmann concludes, from a review of the literature and his own observations that: 1.

Clinically positive cases of tuberculosis react in the majority of cases positively, with the exception of those with advanced marasmus. In these cases the positive reaction has a prognostic signification. Its diagnostic value is subordinate because in all such cases the diagnosis can be made without it. 2, A topical diagnosis is impossible. In suspected cases the positive reaction and the exclusion of tuberculous disease in other organs may call us to repeated examinations and scientific observation, and so represent a not immaterial means of aid in diagnosis. In genital tuberculosis, which is almost exclusively secondary, the interpretation of the reaction is difficult. When there is tuberculosis of other organs the interpretation of the reaction may be very difficult. 3, A satisfactory explanation why a large percentage of persons who are clinically free from tuberculosis react positively cannot be given at present. This must be obtained from more extensive observation and a series of autopsies. A positive reaction is in no way demonstrative of the presence of tuberculosis. 4, A negative result in adults indicates with great probability the absence of tuberculosis. The proof of this likewise can be obtained only through a large series of autopsies.

4. The Ophthalmoreaction in Typhoid Fever. Meroni thus summarizes his results, obtained from the test suggested by Chantemesse of applying typhoid toxines to the conjunctiva for diagnostic purposes. I, The typhoid ophthalmoreaction may occur positively after the lapse of six hours not only in patients with typhoid fever, but also in those suffering from other diseases. 2, After twenty-four hours the positive reaction is met with in typhoid; a negative result indicates the absence of that disease. 3, With regard to the positive occurrence of the reaction it is to be considered that there are exceptions, such as the apparently very rare hypersensitive conjunctivæ, in which severe reactions may be induced by ordinarily indifferent substances. 4, Heating to 60° C. does not destroy the efficiency of the typhoid toxine. 5, The instillation of typhoid extract caused no harmful results in his experiments. 6, The ophthalmoreaction may prove to be of practical service, even though it may not prove to have an absolute diagnostic value,

5. Is the Conjunctival Tuberculin Reaction without Danger?—Görlich shows that positive reactions have been observed with relative frequency in fresh nontuberculous infections, and that they are sometimes followed by serious after effects. He does not consider that the test is one which should be recommended to the practising physician.

6. Cutaneous Inoculation of Tuberculin in Infants.—Morgenroth says that von Pirquet's cutaneous inoculation demonstrated that about five per cent. of the infants under one year of age treated at the clinic in Cologne between August, 1907, and the end of March, 1908, were tuberculous. He finds the cutaneous inoculation with undiluted old tuberculin without previous preparation to be reliable, free from after effects, and harmless to the children. It should be used by practitioners in every case in which the surroundings of the child are plainly tuberculous and a tuberculous disease of the child is to be decisive as to the diagnosis tuberculosis in in-

fants. The not always harmless and frequently unreliable subcutaneous inoculation he no longer uses. Whenever an infant reacts positively to the cutaneous inoculation an investigation of its environment for evident tuberculosis is necessary; almost without exception such a condition can be demonstrated, and as the tuberculous infection of infants very often arises from such surroundings, children during the first year of their lives cannot be removed too early from such dangerous environment. Tuberculosis in infancy he believes to be usually due to inhalation of human tubercle bacilli.

 8. Sporadic Cretinism. Report of a Case,
 By C. F. Judson and W. F. Bradley.
- 1. Public School Education. Keeley considers his subject from the child's physical and from his mental development. In the present ten months of required schooling the control of the child has been transferred from the home to the school, with greatly increased responsibility for the latter. There are 18,000,000 school children in this country under sixteen years of age. Physical training in the schools of New York City is believed to be defective, and more than thirty per cent. of the children have defective vision. Medical inspection of schools, school hygiene, and the sanitary aspects of schools in general in this country leave much to be desired. The author believes that the curricula of the elementary and high schools include much more than are essential to ordinary life. One serious defect of the schools is the absence of religious teaching, also the absence of all teaching of the physiology of the sexual relations. Instruction should also be given as to the nature and influence of alcohol. Objection is offered to the system of prizes and rewards in schools. In general pupils in public schools are not being taught how to live.
- 2. A Plan of Dealing with Atrophic Infants. -Chapin summarizes his plan as follows: 1. Boarding the children in a district of the country in which the conditions are known to be healthful. 2. Constant attention to diet and hygiene on the part of the doctor and the nurse, who should be familiar with this class of cases and competent to deal with them. 3. The infants should be kept as long as necessary until feeding is regulated, and digestion and assimilation are sufficiently improved to result in an increase of weight. This work must be continued during all seasons.

 4. The training up in a given neighborhood of a number of foster mothers who by constantly taking infants into their homes, will become expert in handling them under conditions totally different from those which are offered by the best institutions, and far superior to them.

method has been tried by the Speedwell Society and has been very successful, many lives of neg-

lected children having been saved.

5. The Need of Postgraduate Instruction in Pædiatrics.—Caillé remarks that the young physician beginning his life of service is usually very deficient in his knowledge of pædiatrics. The present facilities for acquiring practical knowledge upon this subject, before going into actual practice, are extremely defective, and yet pædiatric practice signifies half of the general practitioner's work. The value of a postgraduate course is emphasized in the fact that one sees the patient in the dispensary, and then in the hospital ward, where the treatment is carried out in detail, until the termination in recovery or in death and autopsy. The author does not think that making rounds with a large class of students is of much value to the students. Amphitheatre clinics have advantages and drawbacks, the important thing is that the classes are small and the teaching directed to each individual. Great improvement in the teaching of practical pædiatrics is thought to be a requirement of the medical education of the present day.

The Present Status of Experimental Arterial Disease, By I. ADLER.

The Bacteriology of the Puerperal Uterus By W. R. NICHOLSON

1. Splenic Anæmia, Splenectomy, and Recovery.—Lewis records the important case of a young man who had been under his observation from the time of his birth, and who was operated upon for great enlargement of the spleen at the age of seventeen. He was profoundly anæmic and suffered a long time with vomiting of blood and hæmorrhage from the bowels. The diagnosis of enlarged spleen, gastric indigestion, and probable gastric or duodenal ulcer was made, and a posterior gastroenterostomy was performed. The bleeding ceased for a time and the general condition improved, but the spleen continued to enlarge, and splenectomy was performed five months after the operation on the stomach. Recovery resulted, and after three years the patient remained in excellent physical condition. The careful examination of the extirpated spleen resulted in the diagnosis of chronic perisplenitis and interstitial splenitis. results of splenectomy upon the blood are (1) a slight postoperative increase of red corpuscles and acute transitory hyperleucocytosis; (2) decrease of

hæmoglobin, which gradually increases to normal; (3) lymphocytosis of varying duration after four to eight weeks; (4) moderate eosinophilia after

many months.

- 2. Clinical Notes on Laryngeal Tuberculosis. -Robinson notes that laryngeal complications are present in many cases of pulmonary tuberculosis. They may begin as simple catarrhal trouble, but as soon as the mucous membrane is abraded infection may take place. If the condition is discovered in its initial stage it is often possible to prevent extension of the local lesion. The protective and curative treatment which are advocated consists in (1) rest for the larynx, (2) inhalations. The great value of rest has been observed in cases in which tracheotomy has been performed. Surgical measures are not highly approved of. Curettage is occacionally useful, œdema may be relieved by puncture or incision. Punching and excision of tissue are seldom desirable. Applications of lactic acid, orthoform, morphine, and iodoform are often useful. The best results, in the author's experience, have been obtained by means of a perforated zinc mask in the interior of which is a small sponge. sponge is moistened with a mixture of equal parts of creosote, alcohol, and chloroform, is worn constantly except at meals, relieves cough and pain, and very often mitigates a most distressing condi-
- Primary Tuberculosis of the Mesenteric 3-Glands .- Hess reviews the cases in which primary mesenteric gland tuberculosis has been reported and in which the type of bacillus has been differentiated. Such a review shows that in more than sixty per cent. of the cases the bovine type of bacillus is the causative factor. In children the bovine type of bacillus was present in the majority of cases, but in adults the majority of infections were caused by the human variety. As vet it is not possible to distinguish clinically or pathologically the two forms of tuberculosis. In children, as well as in adults, bovine or human tuberculosis may become limited and healed, and the bacilli may die. In contrast to the summary of cases which have been collected, the author reports two cases in children and one in a voung adult which were due to the human variety of bacillus as shown by the morphology, cultural characteristics, and virulence of the isolated strains.
- 4. Blood Cultures in Typhoid Fever.-Epstein states that his studies warrant the following conclusions: 1. The bactericidal influence of the blood in typhoid fever with reference to positive results in blood cultures has been overestimated. Great dilutions of the blood are not essential; a number of media will give good results. 2. The best results were obtained with two per cent. glucose bouillon, two per cent. glucose agar, and ammonium oxalate solution. 3. On the glucose agar the growth of a certain type of colony is diagnostic, and its absence points to the absence of the typhoid bacillus. 4. The bile media were less reliable than the above mentioned. 5. The author's results agree with those obtained by others though the cases were studied late in the disease. 6. The maximum results are obtained in the first and second weeks; there is not vet sufficient proof that the bacilli are in the blood

at the very beginning of the fever. 7. Protracted cases yield positive results if the continuance of the fever is not due to complications. 8. A continued fever lasting several days after the blood is free from typhoid bacilli will seldom prove to be typhoid. 9. A bacillamia in a relapse is due to a new invasion. 10. No definite conclusion can as yet be drawn as to the value of blood cultures in determining prognosis.

5. The Uncertain Results of Suturing Nerves. -Vaughan observes that the successful results from the suturing of nerves bear but a small proportion to the number of operations, and concludes that either the repair of nerves is uncertain and erratic, or that the technique is far from satisfactory. There is manifestly a difference in the regenerative power of different nerves, thus the trifacial will frequently reproduce itself after the removal of segments an inch in length, while the median or ulnar will obstinately resist reunion or regeneration however carefully sutured or favorably conditioned for repair. The prevailing opinion at present is that regeneration is due to proliferation of the cells in the sheath of Schwann. Secondary suture may be as successful as the immediate. Of forty-four operations by Murphy on different nerves there were but seven in which a successful result was obtained.

6. The Pathogenesis of Tabes Dorsalis .- Williams draws the following conclusions: I. Tabes dorsalis is a secondary degeneration in the posterior columns, due to chronic meningitis, usually of syphilitic origin. 2. The arrangement of the meninges surrounding the radicular nerve makes it susceptible to mechanical or toxic injury at that location. The unequal involvement of different fibres of the posterior root is probably due to some peculiarity of structure or arrangement of fasciculi, rather than to any selective toxic influence. 4. The lesions tend toward resolution and arrest though the process may continue during the life of the individual. 5. With arrest regeneration tends to occur in the radicular nerve, that in the anterior root being more significant than the regeneration in the posterior. 6. The otherwise inexplicable vasomotor and cranial nerve symptoms and post mortem findings are thus shown to be necessary concomitants of the tabetic process. 7. The pathogenesis of the polyneuritic manifestations in tabetics is as yet unsettled.

Proceedings of Societies.

All DICAL SOCIETY OF NEW JERSEY

to His Forward Leitz second Annual Meeting, Held in that Mar in luming 18, 11, and 20, 1908.

The Propose Dr. Los ven J. Lin, at Newark, in the Chair,

The Oration in Medicine, by Dr. WILLIAM K. NEWTON, of Paterson, was entitled Joint Affections in Children Caused by Infectious Diseases. He gave two reasons for the ignorance of the general practitioner regarding infectious arthritis and for the lack of fulness and definiteness in the literature upon this subject—the custom of calling all cases of arthritis rheumatism and the attempt to group all these joint affections under the title of Still's disease. Infectious arthritis might be the result of any of the protonness with program organisms. He ex-

cluded those caused by tuberculosis, syphilis, and acute rheumatic fever, and confined his attention to the less understood cases of infectious arthritis, considering their ætiology, pathology, and symptoms.

Endothelioma of the Pleura.—In this paper Dr. HENRY S. PATTERSON, of New York, gave a review of the literature of the subject, including ninetysix cases. A malignant new growth of the pleura should be suspected when bloody fluid was found in the chest. A number of conditions must be excluded in making the diagnosis, particularly tuberculosis, aneurysm, and primary new growth elsewhere. Persistent bloody fluid, not tuberculous, with progressive emaciation, usually accompanied with fever, made up a suggestive picture. Sometimes cells were found in the fluid. The only absolutely sure method of diagnosis, however, was by making a microscopical examination of tissue that had come to the surface by extension or metastasis. The disease must be treated at first by aspiration. The skin might be frozen with ethyl chloride, care being taken to allow the frost to wear off before puncturing. Otherwise the needle would have to go through a tough, leathery laver and run the chance of bending or breaking. The subsequent pain was relieved by local applications and by the coal tar products, with or without morphine. In the last stages morphine to the point of toxic effects was indicated. Symptoms referable to metastasis must be treated as they arose. The only justification for surgical treatment was the presence of a purulent effusion.

Dr. PHILIP MARVEL, of Atlantic City, asked whether the malignant growths of the pleural cavity were more prone to metastases than similar tumors elsewhere.

Dr. CHARLES A. ROSENWASSER, of Newark, thought it important to do all that could be done to afford relief in cases pronounced inoperable, and asked whether Dr. Patterson's experience with methylene blue in cases of inoperable sarcoma had been that the patients had been made more comfortable by its use, and whether life had been prolonged.

Dr. N. L. Wilson, of Elizabeth, said that in sarcoma of the antrum he thought it better to let the tumor alone and simply keep the patient under the

influence of an opiate.

Dr. PATTERSON said that his case was the ninth that had appeared on record in the literature of this country. He should not have been able to recognize the condition had it not been for an article of Dr. Delafield's reporting similar cases. The diagnosis thus made was confirmed at autopsy. Theoretically one would imagine that the pleura, being so rich in lymphatic drainage, would form a primary site from which metastases would be very frequent and extensive; but, on the contrary, the cases in which metastasis was mentioned represented only about twenty per cent. of the total. He had had no experience with the use of methylene blue in this class of cases; and he stated that his reference to malignant growths of the antrum was not in relation to operative interference, but simply as one of the means of climinating primary growths elsewhere than in the pleura.

The Diagnostic Importance of Vomiting in

Childhood was considered in a paper by Dr. ARTHUR STERN, of Flizabeth, with regard to cerebral vomiting, gastroenteric and peritoneal vomiting, prodromal and initial vomiting in acute infections, vomiting in intoxications, vomiting after excitement, vomiting in cardiac insufficiency, vomiting in cases of general neuropathy, and vomiting from miscellaneous causes.

Dr. HENRY L. Coit, of Newark, commended the courage of Dr. Stern in bringing before the society such a common subject as vomiting, and said that it seemed to be the tendency of the general practitioner to ascribe all manifestations of disease to remote causes, the research laboratory being called in to answer all questions of importance. thought that all the papers should not come from the research laboratory or the experiment station. The importance of vomiting had been much magnified, and incorrect diagnoses had been made from it. He called attention to three classes of diseases in which vomiting was a common symptom: Cyclic, or recurrent vomiting he did not consider so frequent as was believed. He had seen cases in which this diagnosis had been made, but in which a good dose of calomel with a regulated diet and possibly some subsequent intestinal antisepsis had cleared up the condition. With congenital pyloric stenosis, a term that one was apt to apply to persistent vomiting in infants, had been grouped another disease known as pyloric spasm. Vomiting was a symptom of so many diseases that it had very little diagnostic value when isolated from other symptoms.

Dr. P. Du B. Bunting, of Elizabeth, stated that in the boroughs of Manhattan and the Bronx, New York, the lives of twelve thousand children were saved annually by the recognition of the diagnostic importance of vomiting. It was not a disease, but a symptom, and must be considered in connection with the other symptoms present. When it was a prominent symptom, the physician was likely to direct his thought to the stomach; but before looking to that organ for the cause of the vomiting, everything else that might produce it should be eliminated.

Dr. J. P. REILLY, of Elizabeth, said that he would mention only the class of cases in children in which there were periodical attacks of vomiting, but in which no definite lesion was discoverable. If, on close observation during one of these attacks, the physician's hand was placed over McBurney's point, he would gain the reputation of being able to diagnosticate appendicitis in infants.

Dr. D. E. ENGLISH, of Milburn, said that chills, fever, and vomiting were usually considered the three important initial symptoms of scarlet fever; but that, of five hundred cases in which this diagnosis had been made, initial vomiting was present in less than fifty per cent. He believed that many of the cases called cyclic vomiting were simply migraine in the infant. In many cases calonel alone would relieve the condition, but he had been giving this drug in combination with sodium with better results than when the calomel was used alone. He had also followed the suggestion of Dr. Coit in regard to dropping the use of boric acid solution in the nursery.

Dr. Wilson believed that most of the cases of vomiting in children afflicted with adenoids were

due to the vitiated and increased secretion going down the back of the pharynx, rather than to the mere presence of the adenoid or the hypertrophied tonsil

The Present Status of the Milk Problem,—Dr. ALEXANDER MCALISTER, of Camden, said that his paper had been written with the object of urging the use of only ideal whole milk for the very young and delicate. Simple methods of dilution or modification, possible in any household, yielded superior results, because of the greater ease with which fresh whole milk could be digested. In every market this ideal whole milk might be obtained for the price of the searching for it; and the market that fell short in this respect could not be shown up too early or too relentlessly.

Dr. Corr said that the movement for pure milk in the United States was supposed to have had its origin in the Medical Society of New Jersey, at a meeting in 1889. It had grown to such proportions that an attempt was now being made to get medical, as distinguished from municipal milk. The government distinguishes three varieties—certified milk, municipal, or inspected, milk, and other milk. The last should always be cooked and not simply pasteurized.

Dr. ROSENWASSER stated that it had been ascertained by the Dependency and Crime Commission that feeding with impure milk in infancy produced dependency in later life, and remarked that in this commission the Medical Society of New Jersey might, at the expense of the State of New Jersey, find a means to carry out investigations and to save the lives of babies and keep them in good health.

Dr. Henry Chavanne, of Salem, said that the cow was now legislated in New Jersey to a standard that was impossible, except with thoroughbreds; and that not a dairy in the State was allowed to send to market milk that did not reach this standard. As no cows except thoroughbreds would produce milk of this standard naturally, the animals were fed on an artificial diet that stimulated them to the highest point of secretion. This resulted in a sacrifice of the proteids of the natural economy, so that not five per cent, of the cows in New Jersey could raise their own offspring without producing diarrhea in them. If the milk of a cow would not nourish its own calf, it was impossible for the more delicate organism of the child to be sustained by this secretion.

The Annual Address by the President was on the subject of medical expert testimony. Dr. Ill expressed regret that the governor of New Jersey had seen fit to appoint but one medical man on the State Board of Health, and this one a retired physician. He stated that the society was working under a disadvantage, owing to a lack of competent legal advice, and suggested that it engage counsel to defend the members in malpractice suits and to do other necessary legal work. He thought that damage suit expenses should be paid by the society. because the accused practitioner was defending not only himself, but every physician in the State. The difference between an ordinary and an expert witness was that one simply stated a fact and the other expressed an opinion. An ordinary witness who did not speak the truth might be presecuted, but an expert could not be reached by the law for expressing a false opinion. The opinions of medical experts carried no weight, because even those that were honest were discredited by what had become a pernicious system; and Dr. Ill thought that the law should be amended so as to make such scandalous conflicts of opinion impossible. The man who sold his opinion should not be allowed to remain a member in good standing in the society. The profession should put an end to a system that was already dead in that it had outlived its usefulness.

The Oration in Surgery, entitled When Shall the Physician Distrust his own Judgment in Surgical Matters? was delivered by Dr. MAURICE H. RICHARDSON, of Boston. It was most important, he said, that the diagnosis be made early enough to check the disease in the beginning; and upon the shoulders of the physician, because he was the first in the field, rested the responsibility as to whether it should be treated medically or surgically. The errors of surgery were often the result of a too favorable prognosis based upon a wrong diagnosis; and the largest proportion of these wrong diagnoses were due to physicians who were not experts in the diagnosis of tumors. The physician should distrust his own judgment when one decision meant death and the other recovery. If there were strong possibilities of a serious or fatal lesion that the differential diagnosis could not rule out and for which the only hope lay in immediate surgical intervention, then must the physician distrust his own opinion, even if that opinion was favorable. It was common for the surgeon to shift to the physician the responsibility for surgical failure. When there was any doubt as to the placing of the responsibility, the surgeon should be eager to assume the burden. There were many cases, also, in which the physician should distrust not only his own judgment, but that of the surgeon. He should distrust the judgment of any surgeon who had failed to make a thorough examination. Surgeons did not always appreciate the weight of responsibility that the physician felt toward the family of his patient in recommending an operation. The more intimate became the association between these two branches of medicine, the better would be the results.

The Influence of Overweight and Underweight on Vitality was the title of a paper by Dr. Brandreff Symonds, of New York. He said that the influence of overweight in determining an increased mortality was less varying than that of some other conditions, such as age, sex, nativity, etc.

Dr. RICHARD C. Newton, of Montelair, said that in looking over the lists prepared by the Actuaries' Society of America he had found that, according to these statistics, in obese subjects heredity apparently had little influence in determining longevity. This seemed to indicate that obesity was a predisposing cause of death. As an extra pound of fat meant an extra mile of capillaries, it was not surprising that fat persons had weak hearts. Commercial travelers were very good risks, outliving their expectation; while the well to do and the well fed did not live so long as the longevity tables said that they should. Probably the reason for the long life of commercial travelers was that traveling itself is when the said to the commercial travelers was that traveling itself is

cent. made a risk bad. Below thirty years of age, these people were good average risks; but after that, if they increased in weight, they became very bad risks. The heart and kidneys stood the strain until middle life, and then began to give way. Man's climacteric was fifty-four years, and many men dropped over at about that age with apoplexy, heart disease, etc. Stout men were better risks in England than in America.

Dr. Alfred C. Woodhull, of Princeton, said that the standard as suggested in Dr. Symond's paper was differently expressed from the standard in the military service, which was more convenient for common use. Under the insurance plan, the increase was a certain percentage, and one had to calculate percentages to obtain it. Under the plan adopted in examining recruits for the military service, if the applicant was up to the height of five feet seven inches, his weight should be about two pounds to the inch; and five pounds must be added for every inch above that height. Overweight and underweight amounted in themselves to little or nothing, being merely indices of certain conditions that led to unfortunate results. Personally, he would lay much more stress upon the vital capacity and the chest expansion. Discharges of any character, whether a pure hæmorrhage or a serous discharge, were more likely to do damage in very fat persons than in those that were not so stout.

Excision of the Stomach for Carcinoma.—Dr. Edward Staehlln, of Newark, reported a case. The tumor involved the pylorus and was as large as a good sized Bartlett pear. The mass was removed, with the greater part of the stomach, and the remaining part of the stomach was fastened to the intestines by an end to end anastomosis. The patient made a rapid recovery. The tumor of the pylorus was proved by the pathological report to be a scirrhus. A small mass on the greater curvature was a myoma composed of smooth muscle fibres. The patient was now in excellent health. Her weight and appearance were normal, as well as her capacity for work. Her diet was general, but she ate frequently and little at a time.

Dr. Reilly said that he should like Dr. Staehlin to give the results of the chemical analysis that had been made before he performed the operation. He then referred to the difficulty in determining the condition of the stomach from any analysis that was at the command of the profession at the present time. He had in mind a case that apparently was one of carcinoma of the stomach. The diagnosis was, however, disputed by a good clinician, on the ground that no tumor was palpable. Dr. Reilly thought that a diagnosis should not be made on this ground alone. He believed that the diagnosis of carcinoma should be made, even with the absence of a tumor, when all the symptoms known to make up a cancerous condition were present. If any good was to be done by operation, the physician must be able to make out the diagnosis long before the appearance of a tumor.

Dr. James T. Wrightson, of Newark, thought that the fact that the patient had had five eighths of her stomach removed, and yet the digestive processes were carried on so actively that she had regained her health, vigor, and ilesh, opened up a

fresh field for thought in regard to the digestive

Dr. Staehlin said that in his case there was a tumor, and the analysis of the stomach contents had proved positive. Even had the analysis been favorable, he should have concluded that an operation ought to be performed. On having the stomach contents analyzed, he had frequently found that such analyses were not very reliable. In cases with such a severe manifestation of malignancy as that in Dr. Reilly's patient, Dr. Staehlin would suggest an exploratory incision, unless the patient's condition was cachectic, and he felt sure that something could be accomplished by operating, because sometimes the stomach was so high up that, even though a tumor existed, it could not be felt.

Tetanus. Its Prevention and Treatment.—In a paper thus entitled Dr. J. HARRIS UNDERWOOD, of Woodbury, said that the most reliable germicide in these cases was a solution of bichloride of mercury. Pure carbolic acid should not be used, because it sealed up the bacilli by coagulating the albumin of the tissues. Patients with superficial wounds should at once receive an injection of 10 c.c. of antitetanic serum. The treatment after the development of the disease was directed to controlling spasm, overcoming the toxines, and supporting the patient's strength until the symptoms had subsided. For the first, chloral and bromides were valuable; for the second, the serum. Two cases of cure in patients with very severe attacks were reported. In the Cooper Hospital, Camden, the mortality had been eighty to ninety per cent. before the use of antitetanic serum,

and forty per cent. since.

Dr. George E. Reading, of Woodbury, said that the value of the serum treatment for tetanus was best shown by the statistics of the St. Louis Hospital, where, prior to 1907, injections were not used until the symptoms of the disease had developed. In that year they began to inject 10 c.c. of antitetanic serum in every suspicious case. Formerly there had been a great many cases followed by death after every Fourth of July; but this year there had developed no cases of tetanus. Even negative evidence as comprehensive as this, said Dr. Reading, acquired a great deal of weight. thought it would be well for all hospitals to adopt the plan of giving a preventive injection to each patient whose case might be open to suspicion. In cases in which serum treatment was not available, Dr. Reading had seen good results from carbolic acid treatment. The statistics from its use abroad were good, and he thought that if it was more generally tried here, they might be good in this coun-He had seen a number of suspicious cases treated by thoroughly washing out the wound with peroxide of hydrogen, and none were followed by tetanus.

Dr. J. H. Bradshaw, of Orange, considered it unfortunate that in the treatment of tetanus after the symptoms had developed the remedies given were almost as dangerous as the disease. The huge doses of morphine, chloral, and other drugs administered would often kill a person in good health.

Dr. Wrightson said that the use of the serum certainly did cure some patients. In one case treated at the City Hospital of Newark, he had no doubt that the outcome without this treatment would have

been fatal. The cost of the serum used in this one

The Annual Address by the Third Vice-President, Dr. Thomas H. Mackenzer, of Trenton, was a brief review of hernia as understood and treated at different epochs by the past and present masters of surgery.

Acute Intestinal Obstruction was the subject of a paper by Dr. Robert M. Curts, of Paterson, who confined himself to a few interesting pointsthe importance of early recognition of the condition and of surgical treatment within thirty-six hours; the relative frequency of the condition, there being one death from it in every three to five hundred deaths from all causes; the helpfulness of having a good mental picture of the intestines; the mortality in the different forms of acute obstruction; the ages of the patients in the different kinds; and where the knowledge of the physician ended and that of the surgeon began. The prognosis was always grave, the only hope being in surgical treatment. Researches had given little clinical aid to the diagnosis. Acute intussusception was the form most readily diagnosticated, being the only one in which the pathological and anatomical relations could be made out with any degree of certainty. The treatment for it was by immediate abdominal section. It was impossible to make a diagnosis of any particular type before an operation, and quite unnecessary. Attempts to do so only delayed what should be an early procedure. The two most important symptoms were severe abdominal pain and inability to pass flatus. The first was common in other visceral diseases, but the second was found only in acue intestinal obstruction.

Dr. T. W. HARVEY, of Orange, said that no condition required more accurate and certain diagnosis or more generous early surgery than acute intestinal obstruction. The diagnosis was made much less frequently to-day than twenty years ago, and operations for its relief were less common now than formerly. The reason was that many cases of abdominal disease that were formerly allowed to go on to obstruction were now cured before that symptom appeared, and the proper treatment of others relieved the obstruction. On the other hand, a new fruitful cause of obstruction was presented by the effects of laparotomy. Dr. Harvey agreed with Dr. Curts that an operation, to be successful, must be done in the first twenty-four hours; and he did not see the advantage of first attempting any other method of forcible reduction. The most important point to decide was that of whether one should do a complete or an incomplete operation. Another point to decide was what should be done to insure the return of normal peristalsis, and just how much evacuation of the bowel would be required to relieve the

Dr. James S. Brown, of Montclair, said that a phase of the treatment of intestinal obstruction to which the attention of the society should be called was that of distention. A Moynihan's tube was placed in the intestines, which were then strung on it. By this means, instead of there being a mass of distended loops of intestine, the bowel was flat. The abdomen could then be opened with comparative ease to seek for the cause of the obstruction.

The Clinical Features and Treatment of Acute

Perforating Gastric and Duodenal Ulcer.-In this paper Dr. Ellsworth Eliot, Jr., of New York, reported ten cases, eight duodenal and two gastric. The two forms were quite similar. Both were occasionally multiple. Perforation was also often multiple. The cases of multiple perforation of the stomach might be divided into those in which there were several perforations in the same ulcer and those in which several perforations occurred in more than one ulcer. In most cases of perforation of an ulcer on the anterior wall, if there was another perforation, it would be found on the posterior wall, just opposite the one on the anterior. The condition was rarely recognized in time for an operation to be successful. The principal symptom was excruciating pain, usually situated between the costal margin and the umbilicus. The most important physical sign was abdominal rigidity, which was constant. Leucocytosis was of particular interest in the diagnosis. In most cases without perforation it is decidedly above the normal; and in perforation it is doubled. Laparotomy was the only rational method of treatment for perforation, and should be performed at the earliest possible moment. The incision should be made at the maximum point of rigid-·ity. Many patients were operated upon under an erroneous diagnosis of appendicitis. This did not make much difference, because the operator could tell that he was not dealing with an appendix case as soon as the abdomen was opened, on account of the character of the fluid. If gastroenterostomy was necessary on account of stenosis of the pylorus, it was better to do it subsequently, and not at the time of the closure of the perforation.

Dr. Gordon K. Dickinson, of Jersey City, said that the medical profession was intensely interested in the pathological diagnostic points in gastric and duodenal conditions. The surgeon was dependent upon the average practitioner for diagnosis, and many a physician would make a diagnosis of dyspepsia and let the condition run on indefinitely. The patient therefore came to the surgeon in an unsatisfactory condition. Every anæmic woman and every person with a chronic, continuous, or relapsing abnormity of the stomach should be so treated as to minimize the possibility of the formation of an ulcer. If the symptoms continued for any length of time, the surgeon should be consulted.

Dr. James S. Brown, of Montclair, said that the symptoms of gastric ulcer and perforation of duodenal ulcer were acute only in typical cases. Unfortunately, however, there were many cases with symptoms of spreading peritonitis in which one was undecided whether the symptoms were due to perforation of the duodenum or pylorus or of the appendix or gallbladder. He thought that even the cases that one was not confident were due to a ruptured duodenal ulcer had about them something that made one doubt that the condition was due to a rupture of either the appendix or the gallbladder. An incision that would cover the field in any case should be made. Pain in the abdomen was relative, one patient suffering severely and another not so much. When the abdomen was distincted and there was a lack of liver flatness, a little difficulty would arise in the diagnosis. The cases in which the abdomen was spenied late, only a small amount of fluid being found, with immense distention, were rapidly fatal.

Dr. Harvey thought it interesting that for the second time during the meeting the operation of gastroenterostomy, which at one time had threatened to connect everyone's stomach with his intestines, had received a check. While he considered that there were legitimate and proper indications for this operation, he doubted if it should be used for drainage or for a bleeding ulcer.

Dr. Gray said that the literature regarding the subject was meagre and the number of cases small. For this reason, one case might be of interest. He had made the failure in diagnosis mentioned in the paper, that of taking a case of perforating gastric ulcer on the anterior wall for one of appendicitis.

Remote Pain Following Abdominal Operations.—In this paper Dr. WILLIAM E. DARNALL, of Atlantic City, confined his attention to the pain that persisted after the patient had left the hospital and had come under the care of the attending physician, who was worried because the operation had not relieved the patient as he had hoped. This pain usually disappeared gradually, but sometimes persisted indefinitely. When a second operation became necessary, observation would show that the condition was due to adhesions. In trying to remove pathological structures the surgeon sometimes forgot that it was important to consider the future welfare of the patient and try to prevent the occurrence of these symptoms following the operation. The bowels should be handled as little and as gently as possible, and should be protected with compresses moistened with hot salt solution. Every effort should be made to eliminate the possibility of the formation of postoperative adhesions. Every clot left might become an organized adhesion or the focus of infection. Abdominal surgery should not be attempted unless the muscles were relaxed and pliable. The incision should be made so long that it would not need to be stretched with retractors. Any raw surface in the abdomen left exposed should be carefully covered. Patients measured the gravity of their condition by the amount of pain they suffered, and if the adhesions produced more pain than the original condition did, they felt that the operation had done no good.

Dr. Elsmore Stites, of Bridgeton, said that in estimating the intensity of pain or its diagnostic value one must remember that reaction to it varied almost indefinitely in different individuals. seemed to him that one should consider whether the pain was a continuation of a previously existing one or was an entirely new symptom. He thought that its character should also be considered and its location, together with the presence or absence of fever. Severe pain of any other than the neurotic form seldom presented itself as a sole symptom, and it seemed to him that when other symptoms of the presence of adhesions were wanting, an operation for the relief of postoperative pain should not be undertaken. The stimulus of an operation, added to the existing instability of the nervous centres, could not fail to awaken many reflexes.

Dr. DARNALL said that all must appreciate the fact that pain was too big a subject to make a single reference to it, for it would take too long to consider even a single group of its causes. The subject took in the whole field of medicine and surgery. Neurotic pain itself is a very wide field, particularly

that associated with hysteria and that in morphin-

The President said that his experience had been that such operations never produced pain unless they displaced an organ so as to impair its mobility.

Dr. Gray thought that in opening the abdomen for the purpose of relieving adhesions, new ones were likely to be produced, just as the adhesions had been formed in the first place.

Reflex Gastric Symptoms a Factor in Surgical Disease of the Abdomen.—In this paper Dr. John P. Reilly, of Elizabeth, spoke of the importance of such symptoms in the early recognition of pathological lesions. They were present at times when the lesion was not in the stomach, but elsewhere in the abdomen.

Dr. Gray had often wondered why a deformed or diseased appendix, particularly in a chronic case, gave rise to gastric pain or other gastric symptoms, and why a gallstone condition with adhesions about the biliary system caused gastric symptoms, including pain. He had sometimes thought that the sympathetic system might be more chargeable with the symptom complex than any other structure, for he believed it possible that the irritation of a diseased appendix or a diseased gallbladder, through the control of disturbances of circulation in the sufferer, might be able to produce the gastric disturbance. In his opinion, exploratory incision should be a last resort, and should not be undertaken lightly, because it is not free from danger. He thought, however, that the value of exploratory incisions must be recognized. When a patient gave a history of having had for a year or more gastric disturbances that had been treated by all available internal methods of treatment without success, one was warranted in opening the abdomen and making an inspection of the stomach.

Dr. EMERY MARVEL, of Atlantic City, said that in no other place in the body were so many reflexes manifested as in the stomach. The middle coat was a development of the plexus of Auerbach, which supplied and controlled the power of the muscle wall of the gastrointestinal tract. The pylorus and the ileocæcal valve were stronger than the rest of this, the former being the stronger of the two, and any irritation was likely to manifest itself there.

(To be continued.)

Book Antices.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Quain's Elements of Inatomy. Editors: EDWARD ALBERT SCHÄFER, LL. D., Sc. D., F. R. S., Professor of Physiology and Histology in the University of Edinburgh: Johnson Symington, M. D., F. R. S., Professor of Anatomy in Queen's College, Belfast; Thomas Hastie Bryce, M. A., M. D., Lecturer in Anatomy, University of Glasgow. In Four Volumes. Vol. I, Embryology. By T. H. Bryce. Illustrated by More than 300 Engravings, Many of which are Colored. Eleventh Edition. London, New York, Bombay, and Calcutta: Longmans, Green, & Co., 1908. Pp. viii-275.

It is only in recent years that the great value of embryology in medicine has been widely recognized; now, however, there will be few to wonder that an entire volume of this great work is devoted to it.

We do not believe that it can be learned thoroughly from books, but certainly Dr. Bryce has here given us as clear an exposition of this difficult subject as it is possible to make for those who are not themselves versed in its literature and familiar by their own observation with its manifestations. Even this treatise must be read again and again by the student if he expects to remember more than the simplest outline of the science. Fortunately, the study is fascinating, though opportunities for its satisfactory prosecution are not at the command of most medical men. However, those who have had a good training in microscopy can do much in a practical way under the guidance of such an excellent teacher as Dr. Bryce, whose precision of description is admirably supplemented by such beautifully clear engravings as those with which this volume is freely supplied. The work of the publishers is in every respect deserving of the greatest praise. It is fitting that such a classical work as Quain's should be kept up by the three great teachers whose names appear upon the title page of the eleventh edition. more than half a century it has been a favorite, and it still deserves to hold its position.

Gayetés d'Esculape, Par les Drs. Witkowski et Cabanès. Paris: A. Maloine, 1909. Pp. 485. (Price, 5 francs.)

One of the authors of this amusing volume (Dr. Cabanès) is known to some extent as an historian of the odd and quaint in medicine, and his collaborator, Dr. Witkowski, is the author of several works dealing with antiquities in medical history. The volume under review forms one of a series of investigations into the quaint and curious in medical Nearly half of the book is taken up with a Rabelaisian account of the origin and development of the enema syringe, which will probably appeal especially to the French mind, characterized as it is by the modern Gallic wit, but it is to be feared that the healthy Anglo-Saxon intelligence will revolt at some of the descriptions and pictorial illustrations, though Hogarth, among English caricaturists, has been drawn upon for some satirical engravings, and the text is replete with sardonic reflections on both the physician and the apothecary, many humorous anecdotes being included. To those who like this sort of thing the book will prove of interest, but beyond the illustrations, which are classical in some respects we do not see how the medical historian is likely to profit by it.

Bericht über den xiv. internationalen Kongress für Hygiene und Demographie. Berlin, 23-20 September, 1907. Bänder II, III, IV. Mit General-Namen-und Sach-Register. Berlin: August Hirschwald, 1908.

These three volumes have quickly followed volume I, which were reviewed in the June 13th number.

Volume II contains the reports of the Sections in Microbiology and Parasitology, in Dietetic Hygiene and Hygienic Physiology, in Hygiene of Childhood and Schools, in Professional Hygiene and Care of the Working Classes, in Combating Infectious Diseases, and in the Care of the Sick. The United States is represented by M. P. Ravenel, of Madison, Wis., with a report on Infection by Food and Contact, the Alimentary Canal as a Portal of Entry for the Tubercle Bacillus; H. W. Wiley, of Washington, D. C., on Pure Food Legislation in the United States; Simon Baruch, of New York, Baths for

the Laboring Class; H. M. Biggs, of New York, on The Part of the Municipal Authorities in the Combat with Tuberculosis; and Dr. Strong, of Manila, on Protective Inoculation Against Plague.

Volume III, divided into two parts, gives the reports of the Sections in Hygiene of Dwellings, Townships, and Waters; in Hygiene of Traffic and Life Saving; in Military, Colonial, and Naval Hygiene: and in Demography. Dr. R. G. Freeman, of New York, reports on the control of milk.

In volume IV we find the discussions and lectures of the sections. V. C. Vaughan, U. S. A., read a paper on Proteid Susceptibility and Immunity, and another on Experimental Immunity to Colon and Typhoid Bacilli; G. M. Kober, of Washington, D. C., read one on the Production of Pure Milk for Infants. Louise G. Rabinowitch, of New York, presented one, in French, on the Method of Reviving Electrocuted Animals; G. M. Kober, of Washington, D. C., furnished one on Dwellings for Laborers; and W. H. Tolman, of New York, wrote on the American Museum of Safety Devices and Industrial Hygiene. This volume contains also a general index of names, and another of the subjects under discussion.

The five volumes give a well defined review of the congress, and they are carefully edited and

well got up.

Diseases of Injuncy and Childhood. Their Dietetic, Hy-gienic, and Medical Treatment. A Textbook Designed for Practitioners and Students in Medicine. By Louis for Practitioners and Students in Medicine. By Louis FISCHER, M. D., Attending Physician to the Willard Parker and Riverside Hospitals of New York City, etc. Second Edition. With 303 Illustrations, Several in Colors, and Twenty-seven Full Page Half Tone and Color Plates. Philadelphia: F. A. Davis Company, 1908. Pp. xxiii-979. (Price, cloth, \$6.50; half morocco, \$8.)

It was only six months after the first appearance of Dr. Fischer's excellent textbook that this second edition was published, a fact that clearly shows that the work has been highly appreciated by the profession. Prominent among the additions in this issue is the section on hypertrophic pyloric stenosis, a condition which the author thinks is not so rare in infancy as is commonly supposed. The subject is well handled. We do not find that glandular fever is considered, but that affection may easily be overlooked, or possibly Dr. Fischer is one of those who do not admit its existence as a separate disease. The book is in every way to be commended, and we expect to see it appear in still other editions.

Books, Pamphlets, Etc., Leccived.

The Arr and V. subation of Subways. By Goorg. A Sopier. Ph. D., Member of the American Society of Civil Engineers, the American Chemical Society, etc. First Edition. First Thousand. New York: John Wiley & Sons, 1908. Pp. 244. (Price, \$2.50.)

Essentials of Refraction. By Thomas G. Atkinson, M. D., Author of Applied Physiology, Associate Professor of Physiology and Neurology in the American College of Medicine and Surgery, Chicago, etc. Chicago: G. P. Enpell and & C. 1907. Pp. 235. (Price, \$1.25.)

Miscellany.

Convalescent Homes in Boston, New York, and Philadelphia.--Morris Loeb, of New York, gives a good list of such institutions in Charities.

August 1, 1908:

Boston and Vicinity.—Convalescent Home of the Massachusetts General Hospital; 33 beds; M. and F. Convalescent Home of the Boston City Hospital; 34 beds; F. and C. Convalescent Home of Massachusetts Homeopathic Hospital; 20 beds; F. and C. Convalescent Home of Children's Hospital; 100 (?) beds; C. St. Luke's Home for Convalescents; 26 beds; F. Milton Home for Convalescents; 23 beds; F. and C. Children's Island Sanatorium; 30 (?) beds; S. C.

New York and Vicinity.-St. Andrew's Convalescent Hospital; winter, 35 beds; summer, 24 beds; F. and C. New York Home for Convalescents; 21 beds; F. Isabella Heimath; 28 beds; M. and F. St. Phoebe's Mission House; 12 beds; F. St. John's Guild; F. and C.; W. Convalescent Home of Henry Street Settlement; The Rest, Grand View on Hudson; 11 beds. St. Eleanor's Home; 44 beds; M., F. and C. Solomon and Betty Loeb Memorial Home for Convalescents; 100 beds; M., F. and C. St. Elizabeth's Convalescent Home (St. Vincent de Paul); 40 beds; F. and C. Caroline Rest; 100 beds; F. and C. Blythedale; 35 (?) beds; F. and C. The Presbyterian Rest; F. Health Home of the Children's Aid Society; 200 beds; M., F. and C. Convalescent and Fresh Air Home; 68 beds; M., F. and C. Holiday Farm for Convalescent Children; 17 beds; C. Riverbend Home for Convalescents; 16 beds; C. The Robin's Nest; 22 beds: C. Babies' Convalescent Home.

Philadelphia and Vicinity.—University, Episcopal, and Jefferson Hospitals maintain convalescent wards within the hospital grounds, which do not seem to fit into the scope of this inquiry. Richardson Home for Convalescents; 75 beds; M., F., and Seaside Home for Invalid Women; 100 beds; F. Children's Sea Shore Home; not exclusively a home for convalescents, but receives large numbers of this class. Jewish Seaside Home for Invalids:

(9) (2) beds; M., F., and C.

Dr. Elias J. Marsh.—Of Dr. Elias J. Marsh, who died at Paterson, N. J., at the end of his seventythird year, August 3d, an army officer of Civil War service writes: "He entered the Army Medical Corps in the spring of 1861 and served always with credit and, on occasions, with distinction until 1870. when to the disadvantage of the service he reentered civil life by resignation. Field duty, chiefly with the cavalry, and, soon after the war, at West Point brought him in contact with numerous officers, by the survivors of whom, and of the cadets of that period, he must be remembered with respect for his ability and affection and admiration for his character. He resigned when on the Pacific Coast and settled in Paterson, where his professional skill, his clear judgment, and his kindly and public spirited disposition soon made him conspicuous. He became in civic as well as in medical affairs a real leader, not through self seeking, but by natural selection. For many years he was a medical director of the Mutual Life Insurance Company of New York, an important office which he admirably administered entirely free in fact and in suspicion from any taint of the scandal which ultimately attacked that corporation. Connection with that great New York company did not interfere with his public work in Paterson as a director of the Danforth Public Library, as an organizer and administrator of a general hospital there, nor with numerous other phases of civic activity. He carried into civil life an excellent development of the better military methods, and, while depriving the army of qualities which ultimately would have developed into those of a broad and vigorous administrator, those were not lost to the world. Dr. Marsh always maintained an affection for the military service and for his old companions, and the army should regret the departure from this life of one who served it well when good service was important, and whose later life reflected credit upon his earlier connection with military affairs, Marsh during the last year of the war was on General Sherman's staff. He was often referred to as "the man who stopped the war," for the reason that he conveyed the orders of General Grant to "stop firing" while Grant and Lee were having the conference which resulted in the termination of the conflict .- Army and Navy Journal.

Public Health and Marine Hospital Service:

Official list of changes of stations and duties of commissioned and other officers of the United States Public Health and Marine Hospital Service for the seven days ending August 5, 1908:

BEAN, L. C., Acting Assistant Surgeon. Granted leave of absence for three days from August 5, 1008.

Carrington, P. M., Surgeon. Detailed to represent the service at the International Congress on Tuberculosis, to be held in Washington, D. C., September 21 to October 3, 1908; granted an extension of leave of absence on account of sickness.

CLARK, T., Passed Assistant Surgeon. Granted leave of absence for one day, July 18, 1908, under paragraph 191, Service Regulations.

CLEAVES, F. H., Acting Assistant Surgeon. Granted leave of absence for twelve days, from August 3, 1908.

CREEL, R. H., Passed Assistant Surgeon. Granted leave of absence for two months, from August 3, 1908, amended

to be effective from August 31, 1908.

Delgado, J. M., Acting Assistant Surgeon. Granted leave of absence for one day, July 30, 1908, under paragraph

210, Service Regulations.

HAMILTON, H. J., Acting Assistant Surgeon. Granted leave of absence for two days.

Herring, R. A., Assistant Surgeon. Granted leave of absence for one day, July 31, 1908, under paragraph 191, Service Regulations.

Hicks, W. R., Acting Assistant Surgeon. Granted leave of absence for fourteen days, from June 1, 1908,

amended so as to grant five days only.

Носентом, М. W., Acting Assistant Surgeon. Granted leave of absence for fifteen days, from August 8, 1908.

Меодw. Н., Pharmacist. Granted leave of absence for

thirty days, from September 1, 1908.

MULLAN, E. H., Assistant Surgeon. Granted leave of absence for seven days, from July 8, 1908, under paragraph 191, Service Regulations

PETTUS, W. J., Assistant Surgeon General. Granted leave of absence for one month and fifteen days, from August 22, 1908, with permission to go beyond the seas

ROWLES, J. A., Acting Assistant Surgeon. Granted leave of absence for five days, from July 29, 1908.

SAFFORD, M. V., Acting Assistant Surgeon. Granted leave of absence for five days, from July 28, 1908. under paragraph 210. Service Regulations.

SAVAGE, WALTER L., Acting Assistant Surgeon. Granted leave of absence for thirty days, from August 8, 1908. SCHWARTZ, LOUIS, Acting Assistant Surgeon. Granted leave of absence for seven days, from August 3, 1908, under paragraph 210, Service Regulations.

STILES, C. W., Chief of Division of Zoology, Hygienic Laboratory. Detailed to attend the annual meeting of the American Public Health Association, Winnipeg,

Canada, August 25 and 26, 1908.
Thomas, A. M., Pharmacist. Directed to report to Surgeon H. W. Austin, chairman of a board of examiners to determine his fitness for promotion to the grade of pharmacist of the second class

Weldon, W. A., Acting Assistant Surgeon. Granted leave of absence for thirty days, from July 30, 1908.

Wertenbaker, C. P., Surgeon. Granted leave of absence for one month, from August 9, 1908.

Wilson, J. G., Acting Assistant Surgeon. Granted leave of absence for one day, July 27, 1908, under paragraph 210, Service Regulations.

Resignation.

Pharmacist R. Miskimon resigned, to take effect August

A board of medical officers was convened to meet at New York, August 5, 1908, for the purpose of making a physical examination of officers of the Revenue Cutter Detail for the board: Passed Assistant Surgeon J. A. Nydegger, chairman; Acting Assistant Surgeon Edward E. Lindman, recorder.

A board of medical officers was convened to meet at San Francisco, Cal., on the call of the chairman, for the purpose of examining Pharmacist Thomas to determine his fitness for promotion to the grade of pharmacist of the second class. Detail for the board: Surgeon H. W. Austin, chairman; Passed Assistant Surgeon W. W. King, recorder.

Army Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Army for the week ending August 8, 1908:

BAYLY, ROZIER C., First Lieutenant, Medical Reserve Corps. Ordered from Fort D. A. Russell, Wyoming, to Camp Emmett Crawford, Wyoming, for duty at field hospital during maneuvres

BOURKE, JAMES, Captain. Ordered from Fort Leavenworth, Kansas, to duty at camp near Fort Riley, Kansas.
Bratton, Thomas S., Major. Ordered from Fort Des

Moines, Iowa, with Second Cavalry to camp near Fort Riley, Kansas.

CARTER, W. FITZHUGH, Major. Granted leave of absence for one month.

DUNCAN, WILLIAM A., Captain. Granted leave of absence

for fifteen days FREELAND, HERBERT L., First Licutenant. Ordered to duty at Camp Emmett Crawford, Wyoming; granted leave of absence for twenty days, about October 1st.

HARRIS, HERBERT I., First Lieutenant. Granted leave of absence for sixteen days after close of maneuvres near Fort D. A. Russell, Wyoming. WELL, PARK, Captain. When relieved from duty at the

HOWELL,

U. S. Military Prison, Fort Leavenworth, Kansas, ordered to the Army General Hospital, Fort Bayard, New Mexico, for duty.

MABEE, JAMES I., Captain. Relieved from duty on the transport Sherman and ordered to Jefferson Barracks, Missouri, for duty; granted leave of absence for two

PALMER, FRED W., Captain. When relieved from duty at the Army General Hospital, Fort Bayard, New Mexico, ordered to Fort Benjamin Harrison, Indiana, for duty.

MUELLER, ARMIN, First Lieutenant. Ordered from Mil-waukee, Wisconsin, to Jefferson Barracks, Missouri, for

STEDMAN, CHESTER J., Captain. Granted leave of absence for three months

- Stone, John H., Major. Ordered from Newport News, Virginia, to the U. S. Military Prison, Fort Leaven-

worth, Kansas, for duty,
Wickline, William A., Captain. Left Leon Springs,
Texas, and arrived at Camp Emmett Crawford, Wyoming, with detachment of Company B, Hospital Corps. The following named First Lieutenants, Medical Reserve Corps, recently appointed from Contract Surgeons, U. S. Army, with rank from July 7, 1908, are ordered to active W. Bayley, Albion McD. Coffey, Harold L. Coffin, George W. Daywalt, Clarance F. Dickenson, John M. Hewitt, David D. Hogan, Leonard S. Hughes, John P. Kelly, H. Newton Kierulff, Clarence C. Kress, Henry F. Lincoln, Thomas S. Lowe, Clemens W. McMillan, Wallace E. Parkman, Henry du R. Phelan, Elias H. Porter, Jesse P. Truax, George B. Tuttle, Harry H. Van Kirk, Elsworth Wilson.

Navy Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Navy for

CARPENTER, D. N., Surgeon. Detached from the naval station, Cavite, P. I., and ordered home to wait orders.

FARWELL, W. G., Passed Assistant Surgeon. Detached from duty at Camp Ellicott, Isthmus of Panama, and ordered to the appeal requiring existing. ordered to the naval recruiting station, Philadelphia, Pa.

HERMESCH, H. R., Assistant Surgeon. Detached from the naval recruiting station, Cincinnati, Ohio, and ordered

to the California.

Mann, W. L., Jr., Acting Assistant Surgeon. Ordered to the Naval Hospital, Newport, R. I.

MINTER, J. M., Assistant Surgeon. Ordered to the naval recruiting station, Cincinnati, Ohio, when discharged from treatment at the Naval Hospital, Mare Island,

MORRIS, L., Surgeon. Detached from the naval torpedo station, Newport, R. I., and ordered to the naval station, Cavite, P. I., sailing from San Francisco, Cal., about September 5th.
Peck, A. E., Passed Assistant Surgeon. Ordered to the

naval torpedo station, Newport, R. I.

URIE, J. F., Surgeon. Placed on the retired list from
August 1, 1908, in accordance with section 1453, Revised Statutes.

Births, Marriages, and Deaths.

A REVIEW OF RECENT WORK ON SPIRILLAR FEVERS.*

By F. Percival Mackie, F. R. C. S. (England), Bombay,

Captain, Indian Medical Service: Assistant to the Director, Bombay
Bacteriological Laboratory; Fellow of the Royal Society of
Medicine; Fellow of the Society of Tropical Medicine and Hygiene; Corresponding Member
of the American Society of
Tropical Medicine.

Published under the Imprimatur of the Amèrican Society of Tropical Medicine.

The association of spirilla with human disease has been recognized since the discovery by Obermeier (1) in 1873 of the organism which bears his name, but it is only during the last few years that the parasitology of this class of fevers has received particular attention.

In the light of facts which were discovered concerning African tick fever, the spirillar diseases which are met with in other parts of the world have been the subject of careful attention, and the results obtained are so important that I think it of interest to pass them in review and to consider some questions which have arisen out of our extended knowl-

Professor Novy and others have suggested that the various relapsing fevers are caused by different spirilla, and it is partly with the object of collecting evidence on this point that this paper has been written. The question concerning the zoological relations of the spirillum will also receive attention and reference will be made to some animal diseases due to spirilla in so far as they throw light on similar phenomena in man.

For the sake of comparison, and to make what may prove to be a purely arbitrary division of the subject, I propose to deal separately with the relapsing fevers which are met with in the four continents and the literature, so far as it is accessible to me, has been examined with that object.

The fevers and their parasites are conveniently referred to as follows: The European disease and the Spirillum Obermeieri; the African disease and the Spirillum Duttoni; the Asian disease and the Spirillum Carteri; and the American disease, with which we may associate the name of Professor Novy (Spirillum Novyi).

*Read by title at the fifth annual meeting of the American Society of Tropical Medicine, held in Baltimore, March 28, 1908.

Pending the decision as to its zoological position the parasite is referred to as a "spirillum" rather than as a "spirochæta."

I. SPIRILLUM OBERMEIERI.

Morphology.—Length, from 12 μ to 45 μ ; breadth, from 0.3 μ to 0.5 μ . The number of curves varies from four to sixteen, and they are sharp and fairly regular. The ends are pointed. No structure can be made out even under the highest powers, though Obermeier (1) described irregularities in the course of the filament which were probably due to commencing degeneration.

Koch originally described one or more flagella at either end of the spirillum, and the observation was confirmed by Karlinski (2).

Quite recently Fraenkel (3) has shown the presence of peritrichous flagella of extreme tenuity like those described by Borrel (4) in the case of Spirillum gallinarum and Spirillum Duttoni.

Provazek (5) and also Schellack (6) believe that these lateral flagella are but artefacts produced by Zettnow's flagella method.

Most observers agree on the absence of an undulating membrane, though such has been described by Schaudinn (7) and also by Leishman (8).

The movements of the spirilla are varied; there are three easily distinguishable. The first is a rapid, corkscrew motion accompanied by translation from one part of the field to another; this is seen at the beginning of an attack, when the parasite is most vigorous. The second consists of an undulatory movement of the whole thread, and is seen as the crisis approaches or when the spirilla are losing their vitality—Weigert (9) and Moczutkowsky (10). The third is a swaying motion and is the last sign of vitality. To these Munch (11) adds tetanic movements.

All observers have failed to cultivate the organism in vitro, though it is capable of surviving as long as a fortnight or more at room temperature (Gabritchewsky) (12). It lives longer in blood drawn early in the disease than at the critical period, and longer at room temperature than in the incubator or in the refrigerator.

The relation of the spiritus to human disease.— They are present in the blood stream from the onset of the fever until the crisis, when they suddenly and totally disappear. They then collect in the spleen (Metchnikoff) (13), (Soudakewich) (14). Many writers have examined the secretions and excretions, and all agree with Engel (15) and Moczutkowsky (16) that the spirillum is never found except in the blood stream. Intrauterine infection of the fœtus has been observed by Albrecht (17). There is a progressive polynuclear leucocytosis falling with or about the time of the crisis.

Transmission to laboratory animals.-Until recently all animals, except monkeys, were stated to be immune, but lately Fulleborn and Martin Meyer (18) and also Uhlenhuth and Haendel (19) have shown that, although mice cannot be infected directly from human sources, yet if the spirillum is first passed through a monkey then infection can be set up in mice. The infection does not seem to be severe, and serial passages cannot be obtained. Inoculation with apyrexial blood is negative (Bullock). Fraenkel (21) noted that some mice became infected by devouring the carcase of a mouse which had died of the disease. Uhlenhuth and Haendel (22) failed to corroborate this, but found that the mice which had so eaten had acquired some degree of immunity. The same experimenters found that monkeys suffered from a severe attack of the disease, which was followed by a relapse. Rats and mice inoculated by the peritoneal route showed a blood infection in twenty-four hours, reaching a maximum in fortyeight hours. Spirilla persisted until the third day, but were then avirulent, owing to the presence of · antibodies.

The question of natural transmission.—This is believed to be due to insect agency, and suspicion has fallen particularly on the bedbug (Cimex lectularius). This insect has therefore come in for a large share of attention, and Tictin (23) and Karlinsky (24) assert to have transmitted relapsing fever by its agency. Their methods are open to criticism, as success was not obtained by infection through bites, but by bruising the bodies of recently fed insects in a mortar and injecting the resulting material into monkeys. They also found that bugs taken from infected dwellings frequently harbored spirilla, and, further, they were able to demonstrate them in the stomach contents of bugs as late as thirty days after feeding. Breinl and Kinghorn (25) tried to transmit both Spirillum Obermeieri and Spirillum Duttoni by bugs, but failed, and concluded that these insects would not be found capable of conveying the disease.

The gaedia of hermaty Inanunity is conferred by an attack, but it is not very marked, nor does it last long.

Metchnikoff (26), writing in 1897, believed that the disappearance of the parasite was due to phagocytic action, which took place principally in the spleen. In support of this view Soudakewitch (27) found that splenectomized monkeys passed through a very severe attack of the disease, in which the crisis failed to appear and death often resulted.

Tictin (29) (working with Spirillum Obermeieri) and Lamb (28) (with Spirillum Carteri) failed to show any difference between normal and spleenless monkeys. Gabritchewsky (30) and Lowenthal (31) showed the existence of active spirillicidal substances in the bleed, the hiercroad up to and beyond the crisis According to them, when these bodies have mached a contempte one precontation of the six

rilla takes place, which marks the crisis, following which they are phagocytosed in the spleen.

Schellack (32) does not believe in the destruction of spirilla by phagocytes, but in extracellular de-

struction in the liver and spleen.

Many observers have demonstrated the presence of spirillicidal substances in the blood and the destructive effect of the serum of recovered animals on active spirilla. These facts have been used to distinguish the various spirillar infections from each other and from other diseases, and have formed the basis of treatment by serum therapy. Gabritschewsky (33) and Lowenthal (34) produced such a serum from horses and injected it into patients suffering from the disease. They reported that the treatment seemed to prevent the occurrence of relapses, but on the whole the results were indefinite.

The course of the disease is unaffected by drugs. Morbid anatomy.—There are no characteristic changes in the organs of persons who have died of relapsing fever; such morbid appearances as are met with are those generally associated with severe septicæmia. Thus, there is marked fatty degeneration of the heart muscle, whilst the spleen and liver are enlarged, and show necrotic patches, which are due either to infarction or to local concentration of

spirillar toxines.

Hæmorrhages are not infrequent, especially in the kidneys. Some degree of bronchitis is constant. The bone marrow shows necrotic patches, which are apparently due to infarction.

2. SPIRILLUM DUTTONI.

Morphology-Ross (35) gives the length as varying from 15 \mu to 45 \mu. Dutton and Todd (36) give 13 / to 43 /, and describe it as having pointed ends, from 2 to 6 undulations, and of uniform staining. The width is given as from 0.2 to 0.4 \(\mu\). They describe certain Y shaped forms. which suggest longitudinal division.

Koch (37) found that the spirillum is longer than the European variety. He failed to find evidence of an undulating membrane or of longitudinal division, and did not see chromatin dots in the course of the spirillum. He saw nothing to suggest a cycle of development either in the human

blood or in the bodies of ticks.

Breinl, Kinghorn, and Garrett (38) state that the length of the individual spirillum is from 14 " to 16 \mu, and they describe refractile dots in the

The question of flagella is controversial. The earlier observers found no evidence of terminal or lateral flagella, but Zettnow (39) describes and figures diffuse peritrichous flagella corresponding closely to those described by Borrel (40) in Spiril-

Breinl, Kinghorn, and Garrett, and later Stephens (41), deny the presence of either undulating membrane or flagella. The last named observer describes, however, a terminal whip at one end and a sheath, adding that he has seen eviscerated forms which have left the sheath still retaining its original

Commenting on this appearance Breinl and his coworkers advance similar arguments used by me in reference to Novy's spirillum, namely, that the so called flagellum is merely part of the empty and extenuated sheath.

Dutton and Todd (42) have recently published some new observations on the morphology of Spirillum Duttoni. The organism, they say, is ribbon shaped and consists of a central core and a periplastic sheath. The latter is continued to form a flagellumlike process and there are no peritrichial flagella. The core is composed of a series of grannules interrupted by lightly staining areas. Median or terminal knot like swellings are frequent, and some thickened individuals suggest longitudinal division. Occasionally they are met with inside both red and white corpuscles, especially just before the crisis. They describe an undulating membrane, also longitudinal division, as not infrequent, and think that conjugation takes place. They also describe a change which the spirillum undergoes in the tissues, which results in a body distinguishable with difficulty from a blood platelet, and they believe it to be a sporocyst.

In the bodies of ticks they find that the spirillum undergoes a sort of encystment, which appears as "a faint blue or red spherical matrix about 5 μ to 7 μ in diameter, in which are imbedded perhaps a score of deep red granules." They believe that these sporocysts may rupture and the granules de-

velop each into a new spirochæta.

Schellack (43) gives the maximum length of the individual as 24 μ , with 8 to 12 undulations, and the width as 0.45 μ . He has not satisfied himself as to the presence of an undulating membrane and believes the peritrichial flagella to be artefacts.

The relation of the spirillum to human disease.— All writers are unanimous in stating that the spirillum is much less common in the human blood than

is the case in other spirillar infections.

Ross (44) goes so far as to say that they may not be found in the first attack, but only in the relapse.

Moffat (45) says they are sometimes "excessively

scarce after the first attack.'

Spirilla have not been found, except in the blood stream. There is a leucocytosis, as in the European disease.

Transmission to animals.—Ross and Milne (46), and again Dutton and Todd (47), found that certain monkeys (cercopithecus, cynocephalus) were susceptible, but that ordinary laboratory animals

were not so.

Breinl, Kinghorn, and Garrett (48), however, found that most ordinary animals were susceptible in varying degrees. Thus white rats were the most so, and to a lesser degree dogs, horses, goats, sheep, rabbits, guinea pigs, rats, and mice, whilst cats, chickens, pigeons, and goldfish were insusceptible. The incubation stage in monkeys (by tick transmission) is five to seven days; each febrile attack lasts three to four days; the animals suffer from three or four relapses at intervals of from five to nineteen days, so that the whole course of the disease in these animals lasts from three to eight weeks (Todd and Dutton). The spirilla are more numerous than in man.

The monkeys only occasionally die, but small animals frequently do,

In rats the incubation stage is only a few hours,

and the duration from one to forty-five days, punctuated by successive relapses. The parasites are very numerous and the mortality high. The virus is exalted by frequent passage.

The infection is capable of passing through a Berkfeld filter fine enough to keep back Bacillus prodigiosus. The passage of the spirillum from mother to feetus, already described in Europe by Albrecht (49) and Spitz (50), has been substantiated by Breinl and Kinghorn (51), working with rats and the African infection.

They draw the following important conclusions:

"(1) Spirillum Duttoni passes through the placenta from the maternal to the fœtal circulation; (2) the majority of fœtuses carried by infected mothers are themselves infected; (3) spirilla are more scanty in the fœtal blood than in the maternal blood, but the placental and maternal blood are equally infected with the parasites; (4) the parasites in fœtal blood show no morphological change; (5) there is no tendency to abort, but few of the young animals reach maturity; (6) the young born of infected mothers possess no marked immunity either to direct inoculation or to the bite of the tick."

Natural transmission.—Transmission by ticks occurs in one of two ways: Either by direct infection from the bite of a tick which has itself previously bitten an infected person, or by the bites of ticks

born of infected females.

Koch (52) showed that when a tick had taken in infected blood the spirilla disappeared from its stomach after a few days and were then to be found on the surface of the ovary, where they underwent multiplication. A considerable proportion of the ova of such a tick were infected. There was no cycle of development in the tick, and the route of the infection was not clear, for spirilla were not formed in the salivary glands.

Koch found that from five to fifteen per cent. (once fifty per cent.) of the ticks taken from infected

huts contained spirilla.

Markham Carter (53) found that six out of thirty-two eggs laid by infected ticks contained spirilla. He speaks of some spirilla in the eggs as undergoing longitudinal division and refers to minor alteration in form. Breinl and Kinghorn tried to transmit the disease by the agency of bedbugs, but failed.

Morbid anatomy.—This has been carefully studied by Levaditi and Manouelian (54) by aid of the silver impregnation process described by the former, and they come to the following conclusion: The spirilla cultivate themselves exclusively in the blood stream, and under no circumstances invade the cellular protoplasm. There is no evidence of any intracellular stage in the evolution of the parasite. The spirillum, they say, causes necrotic foci in the liver, and these foci are visible to the naked eye as soft, yellow patches, and microscopically as areas of cell necrosis. These they believe to be chiefly embolic in origin and only partly due to the action of soluble toxines. They believe that the

Herein this spirillum differs from the Spirillum gallurirum and from Irepenema bulklum, which are both true treate incades. Becauth by described Spirillum Observation as battar present in the interior of splenic cells, but the French observers named look upon them as an agonal invasion.

critical destruction of spirilla is essentially a phagocytic phenomenon, and does not depend at all on the direct intervention of spirillicidal substances. They find that the parasites often occupy the macrophages in curved and ringed shapes, and they consider this to indicate degeneration and not to be resting forms, as Schaudinn and Prowazak believed. Similar curved spirilla are seen coiled around the red blood cells, though these cells are never penetrated. Sawtchanks (55) demonstrated that fixative substances (opsonins) acted on the spirilla of recurrent fever, rendering their phagocytosis more easy.

Levaditi and Roche (56) estimated the influence of opsonins on the mechanism of the crisis and came to the conclusion that the destruction of spirilla at this period was not due either to bacteriolysins or to opsonins, and that the latter only came after the disappearance of the spirilla from the blood stream

3. SPIRILLUM NOVYI.

Morphology.—Our knowledge of this spirillum is due partly to the investigations of Norris, Pappenheimer, and Flournoy (57), but particularly to those of Novy and Knapp (58). These observers give the length of the smallest spirillum as from 7 to 9 μ and of the longer forms as multiples of those numbers, indicating end to end union. There are but two or three turns to the short forms, and the curves are sharp and regular. The American spirillum is shorter and finer than either the African or European. A well marked terminal flagellum is pictured, and the writers say there are no lateral ones. Fraenkel (59) and others, however, working with Novy's spirillum in Europe, differ and find the disposition of the flagella as being identical to that in the other two, that is, peritrichous.

The mechanism of movement is similar to that of the other spirilla described, and division is said to be always transverse and never longitudinal. Norris and his coworkers describe the cultivation of the spirillum in citrated blood, but Novy and Knapp, following their methods, failed to convince themselves that true multiplication took place. latter experimenters have since (60) by following the method adopted by Levaditi (61), who worked with Spirillum gallinarum, Spirillum Duttoni, and Spirillum refringens, succeeded in cultivating the American spirillum in collodion sacs placed in the peritoneal cavities of white rats. The spirilla multiply exceedingly under these conditions, and have been carried through twenty generations. The authors conclude that neither red nor white corpuscles are necessary to the multiplication of the spirilla, and that there cannot therefore be an intracellular stage.

Transmission to animals.—Monkeys, white mice, and tame and wild rats were found susceptible to the American spirillum, and with the exception of the last named all are subject to relapses. White mice are especially susceptible, and show an infection within twenty-four hours of injection, which persists up to the end of the third day. The infection is very heavy.

The mechanism of immunity.—Novy and Knapp (62) have paid special attention to this part of the subject, and their results are thus summarized:

"A powerful specific germicidal body is present in decline and in recovered blood, notably in blood of hyperinimunized rats. This body does not originate after the blood is drawn, but exists within the living animal. An immunizing body is also present, and is probably distinct from the germicidal agent,"

Pfeiffer's phenomenon can be demonstrated in vitro and in vivo. In the peritoneal cavity of hyperimmunized rats the spirilla are killed almost instantly, after which they are taken up by the macrophages or large mononuclear cells. Active immunity follows recovery from the infection. By successive injections of spirillar blood this immunity can be increased to a remarkable degree.

Passive immunity can be imparted by injections of recovered or hyperimmunized blood. Both active and passive immunity may last for months.

Hereditary immunity can be obtained, and is probably the result of infection in utero.

Preventive inoculations can be successfully made in rats, mice, and monkeys. Infected rats, mice, and monkeys can be promptly cured by injection of hyperimmunized blood. Subsequent relapses, if any, can be prevented by curative doses of blood. Agglutination of spirilla occurs in vitro and in vivo under the influence of recovered or hyperimmunized blood. To a slight extent it occurs during crisis. The agglutination, germicidal, and immunizing properties of recovered blood can be used in the serodiagnosis of relapsing fever, and also for the identification of spirilla. The evidence points to the existence of a group of relapsing fevers.

It is not clear whether relapsing fever is indigenous to the American continent, or whether it was originally imported. It appears to be very rare, and clinical descriptions of the disease are not accessible to me.

I am not aware of any theories as to its transmission among human beings.

An outbreak of relapsing fever has recently been described by Franco, of Bogota, in Columbia, South America, and reported by Blanchard (63). The spirillum resembled that of tick fever, and was associated with the bites of ticks, and of these Blanchard incriminated particularly *Ornithodorous turicata*.

4. SPIRILLUM CARTERI AND ASIAN RELAPSING FEVER.

Morphology.—Length, 12 μ to 16 μ , by 0.3 to 0.5 μ wide. These are the measurements of the common form seen in circulating blood, which show no sign of dividing. Shorter individuals measuring 7 to 8 μ are sometimes seen. In the organs of infected lice spirilla only 2 or 3 μ long are seen; these are in the form of a single S curve, and would be irrecognizable were it not for their association with those of normal dimensions.

Novy has noticed the presence of similar short forms in the substance of phagocytes, and it may be that these represent the essential units of which spirilla are composed.

These short individuals show no fragmentation or other sign of degeneration. In the healthy spirillum no structure has been made out, but when degeneration commences the cytoplasm breaks up into minute dotlike segments, which give the chromatin reaction, but are not acid fast.

There is a terminal filament at one or both ends,

similar to those described and figured by Novy as flagella. I have hitherto looked upon these as empty sheaths for reasons already advanced (64).

Multiplication takes place in the circulating blood by transverse division, but recently I have seen appearances in the stomach of the louse which strongly suggest conjugation or longitudinal division.

I have not been able to demonstrate an undulating membrane. Cultivation has not yielded positive results, but multiplication takes place in centrifugalized citrated blood for the first twenty-four hours and then stops.

The spirillum has been recovered alive from blood three weeks after withdrawal from the body.

The relation of the spirillum to human disease,-The spirillum is readily found in the blood during the acute attack, becoming more frequent as the crisis approaches, at which time it completely disap-

The secretions and excretions have since Vandvke Carter's time been held to be free from infection, and some experiments recently performed by me bear out this statement. It is true that several times spirilla of some sort were present in the urine, but inoculation of them into monkeys failed to produce the disease. The spirillum, moreover, is present in the menses, in placental blood, and in the blood from hæmorrhages. A series of cases among the staff of a lying-in hospital in Bombay appeared to be due to infection from placental blood

The apyrexial blood of patients has hitherto been looked upon as incapable of producing the disease, but there is some evidence which throws doubt on that observation. One carefully conducted experiment of mine showed that the spirilla appeared simultaneously in the blood of an inoculated monkey and in the relapse blood of the patient from whom it was taken. The incubation period in the monkey was delayed from the usual three days to five days. Blood taken at the same time from the human patient, citrated and preserved in vitro, did not show

In this connection it may be noted that Albrecht (65) in 1881 showed that blood drawn from patients, either one, two, or three days before a relapse was due, showed a development of spirilla even in vitro, and that the development coincided with

the time of the relapse in the patient.

Dr. Row, of Bombay, has informed me of a sim-

ilar observation on his part.

Carter explained Albrecht's observation by saying that spirilla appear in the blood before the temperature begins to rise, but are scarce and difficult to find, and hence, although Albrecht assumed them to be absent, they were really present, but in such small numbers as to be overlooked.

Transmission to animals.—Carter and subsequent observers failed to produce the disease in any animals except monkeys, but recently I have shown that white mice, white rats, white rabbits, black rats (Mus rattus), brown rats (Mus decumanus), and to a lesser extent guinea pigs, are all susceptible, but dogs, cats, goats, and pigeons are refractory.

The infection in animals other than monkeys is transient, and is not accompanied by marked symp-

toms, and the blood infection is light.

It is possible to infect monkeys by using much

smaller doses of infected blood than that usually employed, and also by light scarification of the skin and application of infected blood. Further, by the use of a grooved needle, to imitate the proboscis of an insect, the infection was carried from an infected to a noninfected monkey by transpuncture. Again, I showed that monkeys readily became infected by feeding with spirillar blood; the incubation stage is prolonged from three to five days, but a typical attack follows.

These experiments show that the agency of insects would probably suffice for transmission, and, further, that such transference is probably mechanical, or, at any rate, does not necessitate the occurrence of any intermediate stage of development.

The question of natural transmission.—Ten carefully organized experiments have been made, at intervals spreading over a year, to transmit the disease from an infected to a noninfected monkey through the agency of bugs. The first experiment was successful, but the nine following ones failed.

No cases of natural transmission have taken place in the monkey room, and no monkey has ever shown

natural or unexplained immunity.

The organs of bugs (Cimex rotundatus) have been examined with minuteness at different stages after an infected feed, and spirilla have been found with regularity up to the sixth day after feeding, but only in the stomach and only in the presence of fresh blood and without sign of multiplication. More definite results have been obtained with the body louse (Pediculus corporis), and the observations on the Nasik epidemic have just been published (66).

Thus fourteen per cent. of lice taken from the heavily infected boys' ward, two per cent. taken from the scantily infected girls' ward, and thirteen per cent. of artificially fed lice showed multiplication of spirilla in the internal organs. The principal seat of multiplication was the stomach of the louse and the upper part of the alimentary tract and the ovaries, and sometimes the Malpighian tubes were secondarily infected. A fluid rich in active spirilla could be obtained by gentle pressure on the heads of infected lice.

The question of immunity.—By injecting the blood of man and monkeys into monkeys and into goats a marked, though not high, degree of immunity was called out. The serum so obtained was found to have the power of killing the spirilla and producing lysis in a short time (fifteen seconds) in dilution of

About 30 c.c. of such serum was injected into a patient during the height of the disease. The result was indefinite.

The observations I have made incline me to believe that the action of spirillicidal substances determines the crisis, and that phagocytosis, if it takes place at all, is carried on in the internal organs, and is of secondary importance.

I have never seen phagocytosis taking place in the blood stream, although I have frequently observed dead spirilla engulfed by leucocytes when both were

kept in vitro.

Lamb found that the spleen was not of such importance in the crisis as Soudakewitch and others had supposed, for he found that spleenless monkeys did not suffer to a greater degree than normal ones. He also carried out experiments to determine the relative importance of phagocytosis and of spirillicidal substances in the mechanism of the crisis. He came to the conclusion that it was the increase of spirillicidal substances which determined the crisis, and that phagocytosis was only secondary. He advanced a theory to explain the recurrence of infection similar to that put forward by Wright and others to explain relapses in enteric fever.

According to this idea, spirilla escape by finding areas protected from the full spirillicidal pressure of the blood and remain there until such pressure has been reduced by excretion or by the production of antispirillicidal bodies. They then are able to recultivate themselves in the blood stream and so

produce a relapse.

Morbid anatomy.—The very careful description of post mortem examinations in Vandyke Carter's monograph (68) serves only to leave the impression that there are no lesions characteristic of the disease. If the tissues are stained by those methods which are usually chosen for revealing bacteria or protozoa, the spirilla are demonstrated with difficulty. They are seen to occupy the bloodvessels and the tissues in the neighborhood of hæmorrhages. From this I believed (69) that the spirillum was a true blood parasite and lived only in the circulating blood. More recently by using Levaditi's silver impregnation method this view has been modified. The spirilla were seen to be scattered throughout the liver, and not confined to the bloodvessels, though it is true no special relation to the tissue cells could be demonstrated.

This observation requires substantiation, but if it is true it tends to bring Spirillum Carteri more into comparison with Spirillum gallinarum and Treponema pallidum than with Spirillum Duttoni, which, as has been shown above (Levaditi and Manouelian) (70), is a true blood parasite.

The course of the relapsing fever in man.—For the account of the European disease I refer the reader to the article Relapsing Fever in Clifford

Allbutt's System of Medicine, i, 1905.

The African tick fever has been well described by Moffat, of Uganda, and the clinical course of the Asian disease has been most fully dealt with by Vandyke Carter. I have not been able to see any clinical descriptions of the American disease, and it is not clear how far the accounts in the American textbooks of medicine are the result of the experience of the writers and how much is taken from the classical description of the European disease.

Having studied the account of the disease from these various sources, I am in a position to call attention to certain points of difference between them.

In Europe the incubation stage varies from five to seven days, and there are generally one and sometimes two relapses. Jaundice of a mild degree is almost invariable, but bears no special relation to fatality. Pregnant women nearly always abort. The mortality varies between four to eighteen per cent., but Rabagliali (71) averages it at not more than five per cent.

The African tick fever is more severe. Moffat (72) believes there is more than one type of the disease in Africa, and contrasts that met with on the

Zambesi with that with which he is acquainted in Uganda. The incubation stage is said to be only of a few hours' duration in the former, while in Uganda it is between seven and ten days. Ross and Milne (73) in their original paper give the incubation period as being from one to five days, but Ross in Clifford Allbutt's System of Medicine (ii, part II, 1907) gives it as three to eight days.

The duration of the initial attack is from three to four days, and the first apprexial period lasts five to eight days (Moffat), one to three weeks (Ross).

The number of relapses is from three to five, and if less Moffat suspects some degree of immunity. There may be as many as eleven relapses.

The disease is very much more severe in the European than in the native, in whom a partial de-

gree of protection may be suspected.

There is a form of pneumonia, disappearing with the crisis, and in which the sputum is loaded with spirilla. Moffat also lays stress on certain eye symptoms which he looks upon as pathognomonic.

No figures as to mortality are given, though in one batch of coolies on the Zambesi the mortality is given as fifty per cent. The Uganda disease is

certainly less severe.

Fraenkel (74) has compared the spirilla met with by Koch in British East Africa with that described by Dutton and Todd in the Congo district. He finds no differences in their morphology or in their action on animals, but immunity against each is powerless to prevent an attack by the other. He concludes that these two spirilla are distinct, and suggests similar relationship between them to those uniting the paratyphoid and the typhoid bacilli.

THE RELAPSING FEVER OF INDIA.

The incubation stage and the first pyrexial period and the first apyrexial interval are each of seven days' duration. Low delirium often appears after the crisis, and disappears at the beginning of the succeeding relapse. One relapse is the rule; next most commonly there is no relapse; more rarely two relapses. Choksy, who has seen 6,000 cases in Bombay in recent years, has only once noted five relapses.

True pneumonia is rare, and I have never seen spirilla in the sputum. Parotitis occurs in ten per cent. of cases. Eye symptoms are rare, and are not

of the type described by Moffat.

When the patient is pregnant, abortion is the

There is a distinct type of spirillar fever called by Carter "the bilious typhus type." It is associated with great enlargement and tenderness of the liver and spleen, with much tympanites and marked jaundice, the presence of muttering delirium, and the absence of a crisis.

The mortality is very high. McCowen (75) had a series of seventy-nine cases in a native regiment. The total mortality was 20.25 per cent., but whereas sixty-one cases of the ordinary type gave a mortality of 6.5 per cent., there was a mortality of 66.6 per cent. among the eighteen cases of the bilious typhus type. Vandyke Carter gives the mortality of all cases as 18.02, but Choksy finds it varying from fifteen per cent. in 1807 to forty-three per cent. In 1901, and averaging thirty-eight per cent. during the last seven years.

The mortality among children in Bombay during that time was only eleven per cent.

It is possible that plague may have influenced the relapsing fever rate in Bombay.

A COMPARISON OF HUMAN SPIRILLA.

Morphology.-The American spirillum is described as being shorter than the other three. Uhlenhuth and Haendel, comparing the European, African and American spirilla, found that the African was the most vigorous and was less typically spiral in shape and formed more open flexures. The American showed the most regular and typical spirals, and was less vigorous, while the European was intermediate. Schellak (77) took great precautions to make accurate comparisons, and found that the flexibility and the intensity of movement of the European was less than the Russian, but greater than the American.

He finds that there is a difference in size; thus the maximum length without sign of division of the African is 24 \(\mu \) and width 0.45 \(\mu : \text{maximum length} \) without sign of division of the American is 17-20 μ and width 0.31 μ; maximum length without sign of division of the European is 19-20 / and width

I was able to compare the American spirillum with the Asian, and I found a markedly different picture, and have no hesitation in saying that the two could be readily distinguished by any one who was familiar with either. The American is shorter than the Bombay spirillum, and the individuals are discrete, instead of forming end to end aggregations, as the latter frequently do. It is also thinner and more delicate, and does not stain so intensely as Spirillum Carteri. The American is typically spiral, the Asian is rarely so. The Spirillum Novyi lie separately, whereas the others generally lie knotted together in twos or threes. Transverse division is more clearly marked than in the Asian

Then as regards cilial disposition. Fraenkel finds the European and the American spirilla possessed of peritrichous flagella. Novy and Knapp described only a terminal flagellum on their spirillum. Zettnow (78) found that Spirillum Duttoni had peritrichous flagella, but the Liverpool workers deny

this, and describe a terminal whip.

I found that the Indian spirillum possessed a terminal filament which did not agree with my conception of a true flagellum. Schellak described lateral polyflagella on all three occidental spirilla, but believes them to be artefacts, splitting of the periplast, due to the various manipulations used in Zettnow's flagellum method.

Leishman (79) has examined the African, Euro-

pean, and Indian spirilla, but doubts whether any distinction could be drawn between them on morphological grounds. He failed to find flagella on any of them, and believes that questions of vitality, etc., suffice to explain the alleged differences of shape and so forth.

All observers are agreed that the Spirillum Duttoni is very scarce in the blood of human beings, and this contrasts markedly with the heavy infection met with in the case of the European and Asian diseases. Otherwise the relation of the spirilla to

the human disease is similar in all.

Transmission to laboratory animals.—Here again there are noteworthy differences.

Spirillum Obermeieri is only transmissible to the smaller laboratory animals after preliminary passage through monkeys, whereas Spirillum Duttoni, Novyi, and Carteri are readily transmissible to a variety of animals. Fraenkel found that the African was more toxic than the American spirillum. Monkeys suffered as many as three and four relapses. Rats and hamsters showed one relapse, and most mice and squirrels inoculated died during the primary attack. The American spirillum does not produce a relapse in monkeys or small rodents, and the latter rarely die from the disease. Uhlenhuth and Haendel found that Spirillum Obermeieri produced a severe attack in monkeys, which was followed by one relapse. Spirillum Carteri is very mild in its effects on animals, only monkeys show any clinical manifestations, and I have never seen one (out of about eighty inoculated) die from the fever. Lamb's (80) experience was similar to mine. The other susceptible animals show no sign of disease, except the presence of spirilla in the blood.

The comparison of the clinical course of the disease met with in the four continents brings to light

some marked differences.

The much greater severity of tick fever, followed as it is by four or five relapses, and the frequency of certain eye symptoms detailed by Moffat, contrast with the relative mildness of the European disease and its low mortality. The Asian type is different in showing a fewer number of relapses and by the occurrence of a very fatal type associated with jaundice and the absence of a crisis. The large mortality of relapsing fever in Bombay contrasts with that met with in selected communities in other parts of India, such as Regiments, Asylums, and Jails, and may be due to high incidence of plague in that city.

The best reason, however, for considering the spirilla to be different varieties is that afforded by the serum reaction. Fraenkel, Uhlenhuth and Haendel, Manteufel, Breinl, Kinghorn, and others

larses, variable, by lice (?) immune, serum without offect on Xxxx;

have shown that animals which are completely immunized against one spirillum are still susceptible to either of the other two. Again, spirillicidal substances formed during the course of the disease only act on their own parasites and Pfeiffer's phenomenon is similarly specific.

I found by testing Spirillum Carteri with serum of animals highly immunized against Spirillum Novyi that they were quite unaffected by it, although they were quickly killed by the serum of animals which had recovered from the Indian dis-

From these data I think we may conclude that the four organisms, although closely related, are not identical, but are different varieties.

The appended table summarizes the points of

divergence.

The following precis of the chief spirillar diseases of animals is appended; it is interesting as showing the morphological similarity of the various spirilla, and so emphasises the fact that such similarity is no criterion of identity, for it is certain that these animal spirilloses are clinically very different from one another and from those affecting

Spirillosis of fowls (Spirillum gallinarum).— Marchoux and Salimbeni (81) described this disease, and showed that it could be transmitted by feeding fowls with blood or excrement of infected fowls or by inoculation with infected blood. They found it was transmitted in nature by a species of

The spirillum loses its virulence in blood or in the juice of the organ after forty-eight hours.

The serum of fowls which have recovered shows some immunizing properties, and the same serum in vitro possesses marked agglutinative and immo-

bilizing action on healthy spirilla.

Writing later on the same subject Levaditi and Manonelia (82) find that the septicæmia is not exclusively due to intravascular growth, but the spirilla invade the various glandular tissues and enter into intimate contact with the cellular elements. The crisis, which terminates the infection, is due to phagocytosis of the spirilla by the macrophages of the spleen and liver. The spirillum is capable of infecting the egg of the fowl.

Levaditi (83) in a further paper describes the development of embryos from infected eggs, and shows that death and maceration of the embryo often follows. He describes the various tissue changes associated with the disease and compares it with the course of infection in hereditary syphilis, which it resembles. As in syphilis, so in fowl spirillosis, the gland most heavily infected is the liver, which filters off the spirilla from the infected mother as the blood passes through the umbilical circulation.

A similar fowl spirillosis has been described from Egypt by Balfour (84), and lately by Reaney (85) from Central India. In both these cases the description given followed closely those given by the previous writers, and ticks were held responsible for transmission, as in the originally described disease; it is probable, therefore, that Spirillum gallinarium is a widespread parasite.

Spirillors of bats. This spirillosis was carefully

described by Nicolle and Comte (86) from Tunis. The spirillum had a length of 12 μ , to 18 μ . by 0.25 \(\mu\). width. It had pointed ends, and multiplied by transverse division. There was no evidence

of undulating membrane or of any internal structure, and its movements were vibratory, contractile, and resulted in displacement.

It was transmissible to healthy bats by inoculation, and the virulence was unaltered by frequent passage. If large doses were given infection was noted in forty-eight hours; if in small doses the appearance was delayed for three, four or five days. Recovery was the rule, but relapses occurred, and later some immunity was established.

Theiler (87), describing spirillosis of cattle in South Africa, was able to transmit the disease from ox to ox and from them to sheep. The disease was specifically distinct from piroplasmosis of cattle. It was transmitted by ticks, the offspring of infected

females.

Dodd (88), reviewing the subject of spirillar diseases of horses, oxen, and sheep, concludes that they are caused by identical organisms. Heanley (89) describes an epidemic of spirillar disease amongst Chinese buffalos; the disease was clinically like Rinderpest or hæmorrhagic septicæmia. The spirilla were from 16 \(\mu \) to 32 \(\mu \) long, and were possessed of 8 to 12 spirals; they were present as blood parasites

Stordy (90), in the same journal, describes the disease in the horse as one of rapid course, followed by extreme emaciation. Spirilla abounded in the blood stream. He was unable to transmit it to

a dog.

Many other descriptions of spirillar disease in animals might be referred to, but those given here will suffice to show how widespread these diseases are, and how similar the parasites are in their main morphological characters to one another and to those affecting man.

THE NATURE OF THE PARASITE.

The spirilla were until recently unhesitatingly placed amongst the bacteria, but in 1904 Schaudinn threw the great weight of his authority against this view. He came to this conclusion as a result of his work (91) on Spirillum Ziemanni and the alternation of its generations in the owl and in the mosquito, and he gave his opinion that the spirochætæ represented the flagellate stage of a sporozoon. He further stated that Spirillum Obermeieri and others were possessed of an undulating membrane, a nucleus, blepharoplast, and flagellum; that is, they were practically identical with trypanosomes. His deductions concerning Spirillum Ziemanni were found later to be of doubtful nature, and latterly he acknowledged that it was very far removed morphologically from the typical spirochætæ.

Since then the trend of opinion, led by Novy, has veered back, and many writers now consider that these organisms are more closely related to the

bacteria than to the protozoa.

Novy and Knapp (92) have accumulated considerable evidence in favor of this view and they lay emphasis on the following points: Spirilla are like the bacteria in that they are structureless, possess multiple flagella, and divide transversely. On the other hand they possess neither nucleus, blepharoplast, nor undulating membrane, as the trypanosomes do. They multiply rapidly in the blood stream, giving rise to a disease which runs a short and severe course, such as is common enough amongst the bacteria, but unusual amongst protozoa.

Trypanosomes are very susceptible to plasmolytic changes, but spirilla, like the bacteria, are very little affected by changes in the osmotic tension of

the fluid in which they are suspended.

Spirilla are again, like bacteria, much more re-

sistent to heat than trypanosomes.

The spirilla retain their form under various conditions, when trypanosomes become degenerated or involuted.

Active immunity is readily called out by infections due to bacteria and spirilla, but only slowly and with great difficulty by trypanosome infection.

They also add that aerotropism is a marked feature of trypanosomes, but is absent in the case

of spirilla and bacteria.

An argument upholding this view and one which I have not seen brought forward is that afforded by the leucocyte reaction. Speaking generally, bacteria, when they affect the leucocyte wave, do so by producing a polynuclear leucocytosis, whilst protozoa generally produce a leucopenia, with a relative increase of large mononuclear leucocytes (malaria, kala-azar, etc.).

Relapsing fevers are characterized by a heavy polynuclear leucocytosis, like the bacterial diseases, and I consider this as a very strong argument in favor of the bacterial affinities of the spirilla.

Some writers persist in the belief that sometimes longitudinal division and even that conjugation takes place, and some recent observations of mine in the case of infected lice lead me to incline towards this

Again, the methods of natural transmission by ticks and perhaps by lice is suggestive rather of a protozoon than a bacterium, but this argument is not so powerful as at first sight appears. Firstly, because no intermediate stage or involution form has yet been found in the body of the insect host, secondly, because insect transmission is not peculiar to protozoal diseases, for the Indian Plague Commission has recently shown (93) that plague can be disseminated by the agency of fleas.

Whilst most writers agree that spirilla differ in their characters from both bacteria and protozoa, there is considerable difference of opinion into which group they should be admitted. Zettnow (94), looking to their cilial disposition, their transverse division, and the absence of an undulating membrane, thinks they approach the bacteria, whilst Prowazek (95), who has observed their penetration into red blood corpuscles, and also on account of their reaction to solutions of sodium chloride and other weak alkalies, upholds their protozoal nature. Both are in favor of establishing a new genus for these parasites. Again, Neufeld and Prowazek (96) incline to the protozoal view because of the behavior of the spirilla to solutions of saponin and of bile salts. Bacteria, they say, are not at all affected by saponin and only the pneumococcus is sensitive to bile salts. Animal cells, however, the protozoa, and with them the spirochætæ, are readily destroyed by those agents.

A very important paper, by Swellengrebel, on the morphology of this group of organisms, has recently appeared (97), but his observations, which are in great detail, can scarcely be adequately dealt with in the limits of this paper. He studied and compared a typical spirillum (Spirillum giganteum) (Migula), and two spirochætæ (Spirochæta Balbiani Laveran and Mesnil, and Spirochæta buccalis).

A few of his most important conclusions are here summarized. All these organisms are possessed of a cell membrane which contains within it a protoplastic structure containing vacuoles, and these latter constitute an osmotic system like that described by Fischer (98) in the true bacteria.

The cell body of spirochætæ and spirilla is elon-

gated, with rounded extremities, the pointed appearance at each end is due to the presence of a periplastic cap (la calotte). The nucleus of Spirillum giganteum and of Spirochæta Balbiani is shaped like a spiral filament and is composed of chromatin and divides longitudinally.

The division of the cell as a whole is transverse. Division of Spirillum giganteum and Spirochæta buccalis is brought about by a nipping in, and results in the formation of a fine filament connecting the two daughter cells.

In Spirochæta Balbiani division is effected by transverse cleavage. At one or both ends of the organism the cells' membrane is prolonged to form la calotte. This process is pointed, and terminates in a fine filament—the flagellum.

Sometimes there is a tuft of cilia (Spirillum giganteum).

The flagella of spirilla and spirochætæ are homologous, and both arise from a chromatin granule. Spirochæta Balbiani has no flagellum, but the chromatin band takes origin from a granule embedded in the periplastic appendage. This periplastic appendage is an alveolar structure which winds around the cell and resembles somewhat an undulating membrane.

Spirochæta buccalis and Spirochæta Balbiani and Bacillus maximus buccalis react similarly to solutions of alkalies and acids and degenerate in the

In conclusion, Swellengrabel sees no valid reason for removing the spirochætæ from the family of Spirillaceæ (Migula), but thinks the family should be widened to admit them.

He divides the spirillaceæ into two families, (a) the flexile spirilla, (b) the nonflexile spirilla. latter group contains the true spirilla, which may be subdivided according to the number and disposition of their flagella.

Those with a single flagellum form the genus vibrio, and those with many the genus spirillum.

Here is his scheme in full:

SPIRILLACE.E (MIGULA).

Cells with rounded extremities forming a part of a spiral. Cell division is transverse, and is generally brought about by transverse cleavage, previous to which the cell increases in length. Sometimes division is accompanied by nipping in of the mother cell. After division the daughter cells remain for some time united by an unbroken filament. The flagella, when present, take their origin from a periplastic sheath cap, and are themselves prolongations of the periplastic appendage.

The calotte gives the cell a pointed appearance. FIRST SUBFAMILY.—Spirillaceæ (new family).

Cells not flexible. Genera. Spirillum and vibrio (of Migula).

SECOND SUBFAMILY.-Spirochætaceæ (new family). The cells are flexible.

First genus. Spirochæta (Ehrenberg). Cells without flagella, with a well developed periplastic appendix, and often showing an alveolar structure. Sometimes there are myonemes in the appendage. Types—Spirochæta plicatilis (Ehrenberg); Spirochæta Balbiani (provisionally).

Second genus. Treponema (Schaudinn). Cells with a flagellum at one and sometimes at both extremities, which is the prolongation of the sheath cap. A periplastic appendage has sometimes been demonstrated. Types: Spirochæta buccalis dentium; Treponema pallidum.

Third genus. Borrelia (new genus). Cells with peritrichial flagella. Type: Spirillum gallinarium.

CYSTITIS. BY ROBERT E. DAVISON, M. D., Pittsburgh, Pa.

The acquisitions to the knowledge of the bladder made in the past decade have been most valuable as well as most gratifying to the physician. Its anatomy and pathology have been practically rewritten, and its symptomatology, through the perfection of new instruments, has been given a better interpretation. The didactic nature of this paper will permit our dwelling for a few moments on some of the most important anatomical findings.

The adult bladder lies within the true pelvis. The bladder at birth lies between the symphysis and the umbilicus. At the ninth year it has descended to adult position, but on distention rises above the symphysis. Not until the twenty-first year does it

reach a permanent location.

The capacity of the bladder is not definite, but variable. The distensibility is remarkable. It may rise above the umbilious, filling almost entirely the abdominal cavity. Most normal bladders hold from 300 c.c. to 500 c.c. of urine without discomfort to the patient. The vesical ligaments bind it quite firmly to the symphysis. The superior and posterior surfaces are covered by the peritonæum. In the male the prostate, seminal vesicles, and rectum are closely related to the bladder, while in the female the ovaries, tubes, uterus, and vagina are important relations.

By cystoscopy the interior architecture of the normal bladder can be beautifully seen. Its cone shape and prevailing salmon tint will first arrest

the attention.

The important structures are seen at the base. The urethra has its origin in the neck, and the fundus lies between the neck and the posterior wall. The body is an indefinite part between the fundus and the apex. The deep red triangular portion of the base is the trigonum. Those two little red points seen at the posterior angles of the trigone are the ureteral The interureteral ligament crosses between the ureteral papillæ. The fundus behind this ligament may become abnormally pouched, which is spoken of by the French writers as the bas fond. The bas fond forms a receptacle for retained urine and microorganisms. It will be observed that the mucous membrane is plicated save over the trigone, void of villi, smooth, glistening, and transparent. Dark bundles of the detrusor muscle can be seen crisscrossing the bladder walls.

Histological examination of the mucosa shows that the bladder is lined with large flat epithelial cells of the squamous type, which may be found abundantly in the urine of the inflamed bladder. Beneath the squamous cells are several layers of cylindrically shaped cells, very much like the epithelium of the upper urinary tract. In fact, it is doubtful if they can be distinguished by the ordinary microscop-

ical examination of the urinary sediment. The plications of the mucous membrane are due to the loose submucosa.

The trabeculated arrangement of the musculature is well adapted to allow the greatest expansion with the least possible damage to the bladder walls. In bladders working against resistance, the muscle bundles may become enormously hypertrophied.

This usually takes the form of trabeculation, and should be considered a pathological condition. In trabeculated bladders the walls may be pouched out between the muscle bundles, forming sacules or cellules. Their presence denotes a weakness of the wall, consequently, in irrigating these bladders. much force must not be used for fear of rupturing

The bladder is very richly supplied with blood. The venous return is mostly by plexuses, which empty from one to another, finally reaching the internal iliac veins through the prostatic plexus in the male, and the vesicovaginal plexus in the female. A better architecture for passive congestion can hardly be imagined, especially when there already exists a circulatory disturbance as is seen in the prostatic.

Sensory impressions pass from the bladder to the second, third, and fourth sacral segments of the cord, and motor impressions, from the eleventh and twelfth dorsal and first lumbar segments to the bladder. With the exception of the trigone the mucous membrane is not very sensitive.

Mucous glands are found about the trigone, which secrete actively in inflammatory conditions of the

The absorptive powers of the bladder are not of

a high order, but ought to be considered when applying local anæsthetics to the mucosa. Ætiology.—Cystitis is inflammation of the blad-Inflammation is the reaction of the tissue to an irritant. In cystitis infection is the irritant. Not-

withstanding, inflammation used in its broadest sense does not necessarily mean infection, however; in cystitis it is in the main correct, and must be always considered in the treatment. When it is recalled that Ford demonstrated the presence of bacteria in the kidneys of fifty per cent. of his laboratory animals, which were apparently healthy, the cause of many of the so called cryptogenetic cases will be evident. Cystitis, howsoever caused, means infection. Pus and microorganisms must be present in the urine. When there is pus there are always organisms, but there may be organisms without pus, as in bacteriuria. Inflammation is not a calamity, as it were, that has befallen the bladder, but must be looked upon as a salutary process. In the words of Adami: "Inflammation is a danger signal, but by no means necessarily a danger. Whenever we observe the outward and visible signs of inflammation we have the indications that something abnormal has occurred in the tissues, something that has brought about a reaction on their part. Thus it is our duty to determine as soon as possible what that something is." The presence of bacteria alone will not produce a cystitis, as may be seen in a typhoid fever patient whose urine may contain the bacillus of Eberth in abundance, yet his bladder may be in a perfectly healthy condition.

The bladder mucosa is very resistant to infection;

something must occur to lower that resistance before there can be an infection.

Thus two factors enter into the cause of cystitis, the predisposing cause, or preparatory, and the direct, or bacterial invasion. The predisposing causes may be grouped under three general headings, as follows: (1) Tramua; (2) congestion; and (3) retention of urine.

Trauma may be considered the predisposing cause in cystitis, following injuries of the bladder wall, as

in catheterization and vesical stone. Congestion may be looked upon as the predisposing cause in cystitis following the ingestion of certain drugs, as cantharides, such practices as excessive venery and masturbation, and remote causes. such as constipation, hæmorrhoids, and cold.

Retention of urine is frequently a predisposing cause of cystitis in men with stricture of the urethra or an enlarged prostate.

Microorganisms are the direct cause. The number of bacteria entering the bladder is legion, and it follows that they cannot all be pathogenic. However, there are certain well defined forms found in cystitis which have been proved by experimentation to be pathogenic. Casper classifies the most common ones in order of frequency, as follows: (1) Bacterium coli commune, (2) streptococcus, (3) proteus of Hauser, (4) bacillus of tuberculosis, (5) Diplococcus ureæ liquifaciens, (6) Staphylococcus ureæ liquifaciens, (7) Streptobacillus anthrocoides, (8) gonococcus, and (9) Bacillus typhosus.

As might be expected, the colon bacillus is first on the list in order of frequency. It enters so much into the infections of the abdominal organs, it seems that its field of invasion is unbounded. One can conceive how readily these bacilli may pass through the kidneys to the bladder, and there infect a prepared soil. It is rather surprising to see the gonococcus eighth on the list, when the frequency of

specific urethritus is considered.

A few of these bacteria throw off ferments which decompose urea, thus forming a carbonate of ammonia. The urine becomes strongly alkaline by the presence of the ammonia, and the mucus in the urine is gelatinized into a ropy, stringy material. This condition is seen in neglected cases of chronic

cystitis with retention of urine.

The chemical reaction of the urine in cystitis is usually acid. It is really of little importance to know the reaction of the urine when considering the treatment of cystitis. The reaction is mostly due to the character of the bacteria present when it varies from the normal, consequently there is not much to be gained by giving alkalies, or acids, to change the natural secretion of the kidneys.

Bacteria may gain entrance to the bladder in many ways. The urethra is a common route. The urethra about the meatus is normally invaded by microorganisms, many of which are pathogenic. It is evident that the bacterial flora depends to a great extent upon the cleanliness of the person. The smegma bacillus is commonly found in the urethra, and it is very difficult to distinguish from the tubercle

The length of the male urethra is highly protective to the bladder from this invasion, but the short female urethra offers very little protection. The frequency of cystitis in women suffering from leucorrhœa, or puerperal infection, is due to their short urethra. Notwithstanding this lack of protection, cystitis is not so common in the female as in the male. This may be due to the proneness of the male to congestions about the prostate, his reckless exposures to gonorrheal infection, and his greater liability to stone in the bladder.

It has only been during the past few years that the descending infections-from the kidneys and ureters-have been given the prominent place in the ætiology of cystitis that they justly deserve. The colon and tubercle infections are common examples of this mode of infection. That some infections take place through the blood stream, the lymph stream, the bladder wall, the colon, the uterus, tubes, and ovaries, is not at all improbable. Women with pyosalpynx are commonly sufferers from attacks of

It is no wonder the bladder is so frequently the seat of inflammation, when it has so many avenues of infection.

Cystitis may be circumscribed or it may be diffused. It may affect only the neck of the bladder, or trigone, or portions of the wall, but the tendency is ever to become a generally diffused inflammation. For clinical purposes, inflammations of the bladder may be divided into acute and chronic, with the understanding, however, that it is an artificial division and not in any way a natural one. Abrupt lines of demarcation are not found in nature, consequently it may be at times the clinician will be puzzled where to assign a given case. Notwithstanding this, it is better to preserve this established terminology, although it may be apparent that a classification based on pathological, or bacterial findings, is a more rational one.

In simple acute cystitis the mucous membrane is red, contrasting with the salmon tint of the healthy bladder, œdematous, hyperæmic, vascular, vessels distended, and the glistening transparency replaced by a dull, velvety, reddish appearance. It may affect the entire mucosa or only circumscribed areas. In the severer cases there are in addition spots of ecchymosis and denuded surfaces from which the epithelium has exfoliated.

Sections of the bladder for microscopical study show in the milder grades the epithelium swollen and the mucosa infiltrated by round cells; in the severe ones the epithelium is lost and the round celled infiltration extending through the entire thickness of the wall.

The urine contains pus, organisms, epithelium, and sometimes blood.

Chronic cystitis often affects the neck and trigone only, but it may be a diffuse cystitis. The mucous membrane is grayish, swollen, thickened, covered with secretion, and occasionally granulations and excrescences are seen which look much like papillomata. Exfoliation of the epithelium is extensive, leaving denuded areas, and in some cases the epithelium may be entirely lost.

Sections of the bladder wall show a deep round celled infiltration throughout its entire depth, and in some instances it has been found in the perivesical tissue. The epithelium is gone, and the tisues are in a state of general fibrosis. The bladder becomes virtually a sac with walls of scar tissue. The tendency of the bladder in this state is to contract, and it nearly always does, excepting when there is urinary obstruction, when dilatation is the rule. The contraction may be so great that bladder capacity is lost, when the urine will dribble from the bladder as fast as the kidneys throw it down. If the fingers are pushed into the pelvis over the pubic arch the bladder may be detected as a round hard mass, feeling not unlike a fibroid tumor.

The urine is loaded with pus, organisms, epithelium, and sometimes stringy mucus and triple phos-

phates.

Occasionally cases of cystitis are seen in which the organisms are either exceedingly virulent or else the resistance of the tissue is very low. Deep ulceration, sloughing, or gangrene are likely to occur. As Adami has pointed out, the inflammation is not excessive, but the irritant is; in fact, the inflammatory reaction is inadequate. The line of treatment follows removal of the irritant and augmentation of the inflammatory reaction by every way possible.

The cardinal symptoms of cystitis are strangury, pain, and purulent urine. In acute cystitis strangury and pain are prominent symptoms, but in chronic they may be entirely absent. There is always pus; there can be no cystitis without pus. Strangury is frequency without increase of the quantity of urine. It is present both day and night, but not quite so bad at night; and is due to the inability of the mucous membrane to expand freely with the increase of urine. The frequency of nervous origin is present by day and absent by night. Pain is chiefly a symptom of the acute form. It may be present constantly whether the bladder is at rest or in action. Usually it is more acute during urination, either just preceding the act or closely follownig it, when the last drops are expelled. In bad cases the patient suffers intense pain with every act of micturition. Beads of cold sweat stand out on his forehead, and his countenance is expressive of great agony. In inflammation about the neck of the bladder, the pain is at the close of urination. The pain is frequently referred to the symphysis, perineum, and the end of the penis. However, there may be referred pains to any region supplied by the sensory nerves coming directly, or anastomosing with the filaments, from the second, third, and fourth sacral segments of the

The amount of pus in the urine varies, and is in direct proportion to the extent of the mucous surface involved. In many urines the pus is so evident that the naked eye may detect it, but on the other hand it may be so slight that the microscope will be required. If the patient voids his urine in three glasses each glass will contain purulent urine, whilst in urethritis the third glass will be clear. The comma shreds seen in the third glass are indicative of prostatitis and not of cystitis.

Cystitis is an inflammatory affection, but not always a febrile affection. In acute cystitis and in the acute exacerbations of the chronic form a rise of temperature may be expected. Especially is this true of children; when seen, however, by the physician there is rarely any fever. In a patient suffering from chronic cystitis, if a sharp rise of temperature comes on with a chill it may signify the onset

of an acute exacerbation or a kidney infection. The so called chronic urinary fever, with its irregular evening rise and morning drop, seen occasionally in old prostatics, invariably means kidney infection. Uncomplicated chronic cystitis is an afebrile affection.

Diagnosis.—The diagnosis of cystitis is not difficult. Strangury, pain, and purulent urine are sufficient to make a diagnosis. If the surgeon wishes to treat his patient intelligently he will not be satisfied with simply making a diagnosis; he will go further, endeavoring to arrive at the cause. At first thought it may appear difficult, and it will be in some cases. However, if the surgeon will gather a correct history, make a careful examination of the urine, and apply ordinary skill in the use of modern instruments and the common rules of physical diagnosis, he will rarely fail in definitely locating the source of the infection.

Gonorrhœal cystitis affects the neck and trigone of the bladder, and seldom extends to its body. The first glass is the cloudiest, because it contains pus from the urethra as well as from the bladder. It is markedly painful, and terminal hæmorrhage is frequent. The surgeon must not mistake gonorrhœal cystitis for tumor of the bladder; sometimes the hæmorrhage is very great. This is the only acute cystitis benefited by irrigation. The relief is so marked when irrigated with a silver nitrate solution that it becomes a valuable therapeutic test in a distinctive diagnosis. A smear of the pus may or may not show the gonococcus.

The mild attacks of cystitis so common in women are generally due to infection passing through the nort urethra from without. The inflammatory reaction is usually adequate to overcome the irritant, and a cure takes place without medical attention.

Cystitis accompanying or following attacks of appendicitis is usually a descending infection coming from a pyelitis, the pyelitis having been caused by the organisms passing through the kidney from the infected area. Sometimes the infected appendix is of sufficient length to come in direct contact with the bladder wall, thus supplying the source of infection.

Formerly it was erroneously taught that the pus in acid urine came from the kidney, and in alkaline urine from the bladder. The older writers reached this conclusion by reasoning from false premises, since they believed that cystitis was due to a change in the chemical constituents of the urine. They were satisfied that alkaline urine in some way set up a cystitis, and had many ingenious theories to prove its truth. In their treatment they endeavored to change the reaction of the urine, and to this day the ear marks of that teaching can be found in almost any textbook on genitourinary diseases.

The cystitis following stone or foreign body in the bladder abates promptly upon their removal.

Cystitis with retention is usually chronic, subject to acute exacerbations. Exposure to cold, excessive drinking of alcoholic beverages, and venery are responsible for many of the acute attacks in these patients. Strangury and pain are pronounced during the acute condition, but ordinarily the only symptom is purulent urine. The prognosis depends on how well the retention can be relieved.

In cystitis following cord lesions with a large residual urine, a cure can hardly be expected. Young reports a few cases benefited by hydraulic stretching of the bladder. The bladder is usually dilated, trabeculated and saculated. The urine contains pus, organisms, ammonia carbonate and triple phosphates, and products of decomposed urine. The urine is constantly dribbling through the urethra from the overflow, and a disagreeable stench surrounds the patient. These bladders should either be regularly catheterized or a retained catheter used with the leg urinal.

The benign tumors may or may not cause a cystitis. There is scarcely any pain or strangury.

Hæmorrhage is the prominent symptom.

The malignant tumors invariably sooner or later set up a cystitis. When disintegration begins fragments of the tumor may be found in the urine.

A general plan should be followed in the examination of patients having urinary symptoms. A concise history must be obtained, including the patient's family history, past history, and his present illness. The urine should be voided in three glasses; women can be directed to void in three vessels, the urine then placed in as many bottles. The urine test must include both a chemical and microscopical examination; the former for albumin and sugar, and the latter for tube casts, pus, and blood. To make a bacteriological examination of the urine the bladder must be aseptically catheterized, which at times becomes necessary to do.

Inspection gives valuable information. Palpation is more important. The rectum should be carefully palpated, and the condition of Cowper's glands, the prostate, and the seminal vesicles determined. In women, besides the rectal, a vaginal examination should be made to determine the condition of the

uterus, tubes, and ovaries.

Sometimes a stone in the female bladder can be felt through the vesicovaginal sæptum. The old practice of forcing the finger through the female urethra to palpate the bladder is not countenanced to-day. Percussion gives little information beyond determining a distended bladder. Auscultation is of no importance. The steel sound is valuable in determining the urethral calibre, and also in diagnosticating stone of the prostatic urethra. In searching for vesical stone it is best to use a stone searcher, for the steel sound may be too short to go over the entire bladder wall. The patient should be catheterized to show the presence or absence of residual urine, and also to determine the bladder capacity. It is important to know the bladder capacity, because the frequency might be due to a contracted bladder. which is not at all rare in severe grades of cystitis. The cystoscope is the most valuable instrument the genitourinary surgeon possesses, and to its perfection is due, in most part, the revolution that has taken place in the treatment of bladder affections. Experience and cerebration must be back of the instrument, and it should be considered rather as a reserved diagnostic procedure, following the exhaustion of other simpler methods of diagnosis. It we start that there eight to be a good and sufficient reason for putting a patient through an examination which, if not painful, is at least most uncomfortable. It may be necessary to determine whether

the kidneys are not the source of the pus, and if they are, which one. In a simple cystoscopy, when there is a pyonephrosis, a stream of pus may be seen pouring out of the ureter; in other less well marked cases the catheterizing cystoscope or segregator will be required. The Röntgen ray is not the valuable diagnostic agent for bladder work as it is for the upper urinary tract. The cystoscope will give more information than the skiagram.

It is not the writer's purpose to discuss the diagnosis and treatment of tuberculosis of the bladder in this paper; however, the chief diagnostic points should be considered, in order that a distinctive diagnosis might be made. The tubercle bacillus, as it is better understood, is more and more recognized as a causative factor in disease. This is as true of the bladder as it is of the rest of the body. The end result of the tubercle on a mucous surface is an ulcer. The coalescence of many of these ulcers is spoken of as tuberculous cystitis. This is a most painful affection, perhaps the most painful of all the bladder infections. In case there is an ulcer present in the bladder, and no apparent cause for it, it is good medicine to make a reserve diagnosis of tubercle infection, for simple ulcers are very rare, and then endeavor to prove the presumption. If upon a careful search of the urine the tubercle bacilli are found, and the smegma bacilli have been excluded, then the diagnosis is positive, but if not found this must not be considered negative evidence. The biological test may then be tried; it is done by injecting a few drops of the urine into the abdominal cavity of the guinea pig, when positive tuber-culous lymphatic glands can be found post mortem. Ophthalmoreaction and the tuberculin test may be of assistance. It is not likely that all these tests will be negative in tuberculous cystitis, but if they should be and the appearance of the ulceration is suspicious, it is best to consider it tuberculous, especially if the urine is alkaline and free of organ-

Prophylaxis.—A great deal has been written on prophylaxis, covering the ground thoroughly and exhaustively; therefore, the only excuse the author has to offer for bringing this subject into his paper is its vast importance, and to sound once more the danger of careless instrumentation of the urethra and bladder. The simplest and best aseptic technique should be instituted and followed routinely The external genitalia scrubbed with soap and water, and douched with an antiseptic solution. The anterior urethra irrigated with a solution mildly antiseptic. The lower abdomen, external genitalia, groins, and thighs of patient covered with sterile towels, or towels wrung out of an antiseptic solution. The instruments must be sterile and kept sterile till used. The operator's hands should be cleansed thoroughly, or better, sterile rubber gloves

Treatment.—Scarcely more than principles of treatment can be considered in a brief paper. The physician should first unload his memory of all textbook prescriptions, so called bladder mixtures and cystitis cures. The common sense tenets of general medicine prevail in the treatment of the bladder, as they do in the treatment of any other organ. A full appreciation of the pathology to be

met is necessary, and then the physician should endeavor to promptly meet it. "If we incise or otherwise operate, our object must be not primarily to reduce the inflammation, but to remove the irritant. If we determine that operation is inadvisable, then first we must secure physiological rest for the inflamed part, so that there be no waste of energy on the part of the tissues, that energy being devoted to its fullest to counteracting the irritant."

There are certain general principles of treatment to be observed applicable to all cases of cystitis.

The patient should drink freely of pure water. There is no advantage in the advertised mineral waters. The bowels should be opened and kept well open. The food should be light and bland, but nutritious; liquid food is sometimes advantageous, because it enables the patient to take more water, but this mode of treatment must not be pushed to the point of malnutrition. Alcoholic beverages should be prohibited excepting in weak old people, when they are permissible. The sickroom should have plenty of fresh air, and better if the patient can be kept out of doors. The aged should be gotten out of bed at the earliest possible moment. Tonic and roborant treatment are frequently required. Urotropin should be administered in doses ranging from one to four grammes daily.

It follows from these statements that the general health must be cared for, the hygienic surroundings the best possible, and all the excretory systems

brought freely into play.

Treatment of acute cystitis. The patient must be put to bed with the hips elevated. Strangury and pain will demand attention from the first visit. Heat and the anodynes are the best remedies to relieve the patient. Heat may be applied by the full bath, by the sitz bath, by the hot water bottle, and by rectal and vaginal douches. Of the anodynes, injections hypodermically of morphine combined with atropine act very promptly. Rectal suppositories of opium and hyoscyamus, twenty drop doses of the tincture of hyoscyamus or tincture of belladonna, act kindly. Sinapisms over the hypogastrium sometimes afford relief.

Infusion of buchu leaves seems to possess a curative value besides its diluent effect on the urine. Two teaspoonfuls of the leaves may be boiled in six ounces of water, and this quantity taken several times a day. For acute gonorrheal cystitis, irrigations of silver nitrate solution give the best results. A I in 2,000 or I in 1,000 solution of argentic nitrate is run slowly into the bladder through a catheter using 200 to 300 c.c. This may be done every other day. With the exception which I noted, irrigations should never be given in acute cystitis. If practicable all instrumentation of the urethra

and bladder should be avoided.

In the course of a week or ten days strangury and pain abate, and the patient feels fairly comfortable, i. e., in an average case. If the reaction has been adequate to overcome the irritant the patient will go on to complete recovery, and no treatment applied directly to the mucosa will be required. Unfortunately, this happy event too rarely happens, and frequently the surgeon sees his acute cases pass insidiously into the chronic form.

Treatment of chronic cystitis. Usually if the pa-

tient has been carefully treated during the acute attack the chronic cystitis is readily cured by a few irrigations of a boric acid solution. The chronic cystitis following a neglected or a badly treated acute cystitis presents an entirely different pathology. Strangury and pain are not prominent symptoms save during the acute exacerbations. The bladder wall is in a state of fibrosis, anæmic, thickened, and covered with pus. The treatment naturally suggests itself. Remove the cause, if possible, cleanse the bladder by irrigations, augment the inflammatory reaction, improve the local blood supply, and strive to aid absorption by the administration of potassium iodide.

Bladder irrigations come nearer fulfilling the requirements of treatment than any other procedure known. The irrigations must be given properly, intelligently, and the quantity must be sufficient to distend the bladder walls. It has not only a cleansing effect, but a hyperæmia is caused by the bladder distention. The irrigation may be repeated as often as is necessary to keep the bladder clean. In very filthy bladders, when the irrigations have to be repeated every few hours, it is best to insert a retained catheter. However, if there is much inflammation about the neck of the bladder, the patient will complain bitterly of the pain, and it may have to be re-

moved.

The irrigating solution may be plain sterile water. A very soothing solution is Thompson's fluid, which is composed of borax, sodium chloride, glycerin, and water. Boric acid, I in 50, is also very agreeable. The best results will be obtained by using the antiseptic solutions. The following are standard solutions: Argentic nitrate, I in 2,000 or I in 1,000; potassium permanganate, I in 6,000; bichloride of mercury, I in 60,000; oxycyanide of mercury, I in 40,000. It is a good plan to change the solution from day to day.

In the badly contracted bladder, Young, of Baltimore, has got very satisfactory results by using hydraulic stretching. That the method is safe in selected cases cannot be denied. The writer has seen some gratifying results follow this treatment in Dr.

Young's clinic.

In chrone cystitis of the female the short urethra will permit topical applications to be easily made. These prove very effective in the circumscribed cases. A ten per cent, solution of silver nitrate is

applied through the Kelly cystoscope.

The author is not in sympathy with the cystotomies done for the relief of cystitis in women or in men. It is questionable whether they should ever be done, with the possible exception of cystitis caused by a malignant growth in the bladder. The procedure is opposed in every sense to the pathology present.

Conclusions.

- I. Cystitis is an infection of the bladder.
- 2. The source of infection should be determined, and eradicated if possible.
- 3. When the surgeon is puzzled what is best to do for the patient, he must not make a hole in the bladder without a full appreciation of the results of such an operation.

4. A full knowledge of the pathology in a given

case is the key to the successful treatment of that

In the preparation of this paper the author has drawn freely from the writings of Adami, Caspar, Ford, Kelly, Keyes, Piersol, Skene, White, and

632 FULTON BUILDING.

TWO UNUSUAL CYSTOSCOPIC PICTURES.*

By J. Bentley Squier, M. D., New York.

The writer has chosen to report the following two cases before this association, one simply as a matter of interesting observation and record, the other hoping that it will draw out some discussion which will aid him in the management of it.

CASE I.—The first patient is a gentleman, sixty-three years of age, who presented himself with symptoms of prostatism of a year's duration. The most distressing condition was frequency of urination, which had become so intense that he would have to urinate every hour during the day and four or five times at night. Associated with this was severe pain across the loin. By rectum, one could feel a small, hard prostate gland. He had two ounces of residual urine. Cystoscopy being decided upon to ascertain the presence of median obstruction, an interesting picture presented itself. There was present a prominent median lobe, which undoubtedly was the cause of his prostatic symptoms, and in addition to this four definite ureteral openings. Squirting from each the characteristic swirl of urine could be distinctly seen. Two openings were normally placed at either end of the interuteric fold, the other two, one on either side, were anterior to these and some-what externally placed. Unfortunately, the patient refused to allow catheterization of these openings, as I had hoped to catheterize them with a stilletted catheter and then have a radiograph taken. I hope to persuade the patient to allow me to do this, as it is rather an interesting anatomical

The second case is one of ureteritis cystica chronica and is of such rarity that scarcely fifty cases have been reported. The majority of these have been discovered at autopsy, the patient dying of some intercurrent disease. In the cases already reported the condition of ureteritis cystica had also been more or less constant. As the ætiological factor of this rare condition is still uncertain I will give the patient's history in detail.

CASE II.—The patient was born in 1859, a healthy, normal child. He had the ordinary diseases of childhood. When fifteen years of age (1874) he was thrown from his horse, his foot catching in the stirrup, and he was dragged for a considerable distance before freeing himself. Following this accident the most serious result was the development of an attack of hæmaturia, which lasted a few days and subsided after rest in bed and expectant treatment only. No other urinary symptoms were noticed until 1882, when frequency of urination and burning at the vesical neck developed from apparently no exciting cause. The passage of a sound a few times relieved the discomfort. In 1888 he was refused a life insurance policy because of the presence of pus in the urine. This was the first time that he had any knowledge of an existing pyuria. In 1902, fol-lowing a large dose of quinine which he took for malaria (? symptoms malaise only, no chill or temperature), hæmaturia developed. As there was no pain attending the bleeding, this was considered by the attending physician to be due to the action of the drug. The hæmaturia lasted a few hours. Since this attack of hematuria he has had at intervals of a year or so two other attacks of hematuria. During the second attack, which developed while on a railroad train, he "felt something give way in the right groin," but there was no severe pain or any suggestion of renal colic. The hæmaturia disappeared in twenty-four hours and the patient did not lay up or refrain from going to business. to V order a Good armary Surger

So much for the hæmaturia, but to the patient's knowledge the pyuria had been present ever since the insurance examination in 1888, and the knowledge of this had been the only source of discomfort or anxiety to him. His general health had been excellent. The patient was married and has four healthy children. There was no venereal history; the only serious illness which he had had was an attack of typhoid fever in 1896. Ten years ago the patient had been treated for pyuria by bladder irrigation, etc., and urinary antiseptics. Two years ago a prominent cystoscopist is said to have demonstrated pus coming from both ureteral

To sum up the most salient features of his case, these facts stand out: 1, Pyuria known to be present for twenty years. 2, Four attacks of mild hæmaturia lasting but a few hours with no history of renal colic. 3, No relief from pyuria by bladder treatment carried out by competent hands. 4, No apparent ill effects as yet from it, patient in good health. 5, Increased frequency of urination during the day only, the interval being every two hours.

The patient reported first to me in January of this year. He had just been through a thorough radiographic examination by Dr. Lewis Gregory Cole, of New York, who reported as follows:

Diagnosis: "From study of the radiographic plates one is justified in making a negative diagnosis of renal or ureteral calculus of sufficient size to warrant operation. In the first plate of the bladder region the bladder was full of urine and was distended. In the next of this region the patient had just urinated, and if the bladder was empty then I believe that the walls are greatly thickened."

The uranalysis, which was made by Dr. Sondern, I give in

full with his remarks.

URANALYSIS.

| Reaction,acid, |
|--|
| Sediment,moderate, |
| Nature of the sediment,heavy, |
| Albumin, heat and acid test, marked trace, |
| Albumin, nitromagnesium test,marked trace, |
| Amount, Esbach test,same, |
| Bile pigment,negative, |
| Urea, |
| Indican,no excess, |
| Color,pale amber, |
| Odor,not offensive, |
| Specific gravity, |
| Sugar, cupric test,negative, |
| Sugar, bismuth test,negative, |
| Amount,none, |
| Acetone,negative, |
| Chlorides, |
| Phosphates, no excess. |
| |

| EXAMINATION OF SEDIMENT, |
|---|
| Obtained by centrifuge at 1,800 revolutions for five minute |
| Blood,none, |
| Pus,moderate amount, |
| Mucus,small amount, |
| Casts,none found, |
| Bacteria, no tubercle bacilli found |
| Epithelium,few bladder cells, |
| Crystalline and amorphous matter, .none, |
| Other structuresnone. |

Remarks: The specimen contains more albumin than I believe the pus present would account for, but no renal ele ments could be found microscopically with a lowered gravity and a corresponding relative amount of urea. There are no microscopical evidences to indicate that the pus is of renal origin, but the general character of the specimen creates some suspicion in this direction. A careful search for tubercle bacilli resulted negatively.

A cystoscopic examination made by Dr. James Pedersen and the writer presented a picture of a bladder whose base was studded with multiple cystic nodules varying greatly in size from the proverbial millet seed to the size of a small The largest cyst occupied the centre of the intrathe cystoscopic lamp. Ureteral catheterization was impossible with the direct instrument of Dr. Brown, owing

to the cystic formation obstructing the catheters in their entrance to the ureter. Unfortunately, I have as yet been unable to obtain a distinctive renal examination, as the patient has objected to further attempts at ureteral catheterization, even by the indirect cystoscope. From January, when I first saw him, until the first of this month, the patient has been under local treatment with practically no

diminution in the amount of pus in the urine.

Two weeks ago the patient was operated upon for excision of varicose veins of the leg. A few days after the operation a very marked increase of pus appeared in the urine with difficulty in voiding it and increased frequency. At the end of the act a few drachms of creamy, sticky pus would be voided with some stringy detritus made up of mucus, pus, and red blood cells. This existed for five days, when the creamy pus disappeared, the urine assumed its usual milky look, and the patient began to have an elevation of temperature, which elevation lasted for three days, the highest of which was 102.5° F. Whether the anæsthetic caused a lighting up of the inflammation, or whether some of the cysts evacuated themselves, leaving a raw surface for the absorption of infection, is merely conjecture.

Cystitis and ureteritis cystica chronica from the standpoint of the pathologist has been recognized for a long time. Dr. Bond Stowe, in a report of the autopsy findings of ureteritis cystica chronica read before the New York Pathological Society in February, 1907, has brought the literature up to date. There seems to be contention in its causation: (a) Parasitic origin; (b) degenerate epithelial origin, or retention cyst.

Giani, of Turin, Italy, has produced cystica chronica by inserting foreign bodies in the bladder of rabbits and also by curetting its surface. The presence of local inflammation seems necessary for its existence. The weight of evidence is against

the parasitic (protozoa) theory.

The questions which suggest themselves in reviewing the history are these: How much will the presence of the pus in the urine jeopardize the patient's chance of longevity in view of the fact that the disease is usually accidentally discovered at autopsy? What conservative local treatment will benefit him? What operative treatment can be offered if ablation of the mucous membrane has caused the cystitis to occur in animals?

20 EAST FORTY-SIXTH STREET.

CARSICKNESS.

By Ira S. Wile, M. S., M. D., New York,

Clinical Pathologist, Children's Department, Vanderbilt Clinic.

The commonest aberrant conditions often pass unnoticed in medical literature while the rarest para-

site will provoke volumes of discussion.

Considering the frequency of seasickness, little is known of its frequency, ætiology, pathology, se-

quelæ, or true therapeutics.

Carsickness is a very common condition, belonging to the same category of medical ailments as seasickness, though apparently not identical with it. A hunt for literature upon this subject scarcely repays the hunter. Its most noticeable feature is its paucity. Carsickness is referred to, at times, in an offhand way when the subject considered is seasickness. As Beard notes, "seasickness is not confined to sea—one may be seasick on land."

By carsickness is meant the series of unpleasant symptoms as giddiness, staggering, nausea, vomiting, etc., due to riding in a car, horse, steam, or electric automobile, or baby carriage.

A rational consideration of carsickness requires at least a consideration of the literature of seasickness. As the two conditions are largely regarded as identical in ætiology, we must critically consider the various theories held to account for the unpleasant phenomena attendant upon them.

Shelmerdine (1) deems seasickness a motor neurosis. He regards the condition as the result of a

lack of proper balancing.

Sumner (2) believes in the psychic origin of seasickness. He attributes the condition to the confounding of old ideas of perpendicular and angular planes. This idea is well expressed by him: "Here we have the unusual vision of objects flying towards us and these impressions with some people come into conflict with the standard firmly fixed in mind for such things as trees and fences and ground. This struggle to associate the unusual with the usual results in the well known sickness."

Darnall (3) regards seasickness as a symptom rather than a disease. He places the ætiological factor in a disturbance of the sense of equilibration. He recognizes that the vomiting reflex is in intimate relation with the whole organism. Much of the condition is regarded as an evidence of motion transmitted to the endolymph. Stress is laid upon the proximity to each other of the nuclei of

the eighth nerve and the vomiting centre.

Barnett (4), in considering the ætiological sources, dismisses the stomach as overrated; discards the liver as an impossible cause. The nervous system is regarded by him as all important. As an exciting cause, the motion of the boat is considered. Especial importance is placed upon the connection of the auditory and vagus nerves through the facial nerve. The true cause exists in an irritation of the terminal fibres of the branch of the auditory nerve distributed to the membranes of the semicircular canals. To quote exactly: "Any motion which is contrary to that usually experienced by the fluid contained in the semicircular canals will cause a set of symptoms exactly similar to those of seasickness." He divides the symptoms into those referable to (a) the semicircular canals, (b) the brain, (c) the stomach.

Waugh (5) attributes seasickness to the psychic influences of thinking of it. The direct cause he

believes to be cerebral anæmia.

Beard (6) regards seasickness as a functional disease of the central nervous system. Mechanical agitation is the basis of his theory of origin. Because vomiting is a symptom of cerebral concussion, he interprets seasickness as the result of a series of mild concussions. He appreciates the fact that train motion, swinging, rocking, etc., may produce a similar set of symptoms from the same cause.

This brief résumé presents some of the ideas presented to account for seasickness and its congener carsickness. A consideration of the application of these views to carsickness is interesting.

Is carsickness a neurosis? A neurosis is "an abnormal nervous action or affection of the nerves or nerve centres of a functional nature." As far as is known, there is no appreciable organic alteration of tissue causing carsickness, so it may be termed a functional neurosis. Carsickness is a reflex neurosis, being "a functional nervous lisease

whose origin resides in some irritation or part distant from that in which the affection is manifested."

Classing carsickness among the reflex neuroses, still makes it necessary to further account for its origin. Many points of origin have been suggested for seasickness and they must be studied with reference to their applicability to carsickness.

Irritation of the optic nerve or vestibular nerve is a satisfactory cause to many observers. Cerebral concussion or a psychic origin suffices for others. The stomach supplies an all sufficient cause for a

few investigators.

While seasickness and carsickness belong to the same general category of neuroses, they are not necessarily identical in origin nor course. Individuals who are carsick may be first class sailors, not knowing seasickness at any time. Poor sailors, vice versa, who are prostrated almost as soon as they set foot on a boat, may never know what carsickness means despite prolonged car journeys. Seasickness rarely affects the extremes of life—infancy and old age. Beard is correct, however, in stating that "even young children do suffer somewhat from seasickness. Carsickness is comparatively common in infancy—and old age is not free from it. In fact true carsickness usually begins during infancy or childhood.

Seasickness and carsickness are alike in being much more frequent among females than males, possibly owing to inherent differences in the organization of their nervous systems. Carsickness presents an interesting phase not noted in seasickness. An inherited tendency to carsickness appears to be handed down in the female line. I have found quite frequently carsickness in three generations of a family and only in the female members thereof. In two series of three generations, where the question was asked, seasickness was not a common experience. In one series, the grandmother and mother both came from Germany and did not suffer from mal de mer. Both were sufferers from carsickness. The mother had suffered from infancy. Her child was carsick at six weeks of age, the first time it was taken for a trolley ride.

Is carsickness due to a lack of proper balance? equilibrium is "a state in which all the skeletal muscles are under control of nerve centres so that they combine, when required to resist the effect of gravity or to execute some coordinated motion." It is very apparent that the sense of equilibrium can only result from the sum total of all sensory impressions. Sight, audition, olfaction, tactile sensation, vestibular sensation, muscular sense, all contribute to the sum of sensations essential for a sense of equilibrium. If any part of the sensory impressions is erroneous or departs from the individual normal, a disturbance of the sense of equilibrium results, and certain reflex conditions, such as nausea, pallor, rapid pulse, clammy skin, vomiting, etc., ensue.

If this view of equilibrium is accepted, carsickness may be said to be due to a lack of sense of equilibrium.

The question then arises, Which sensory impression is distorted in carsickness? Is it one sense or all the senses which lie at the bottom of carsickness? In seasickness a person may become seasick from seeing the motion of the waves (visual), feel-

ing the motion of the boat (vestibular), smelling the oil (olfactory), hearing the noise of the machinery (auditory), seeing another person retch (psychic and visual), sympathizing with a wretched fellow traveler (psychic), overeating (gastric), sense of fear (psychic), sight of food (visual), smell of food (olfactory), taste of food (gustatory), thought of food (psychic), inability to walk (muscular), etc. Any one of these causes may operate to cause a lack of true sense impressions, and as a result seasickness ensues.

Adults usually account for their carsickness on the basis of the motion of the cars. They feel the motion of the cars after they have gotten off the cars. When carsickness begins in adult life, it is almost as frequently found in males as in females. Visual defects are usually the origin. With the correction of errors of vision, the carsickness disappears. In women, uterine displacements are not uncommon predisposing causes of carsickness. The psychic, auditory, or olfactory senses are rarely causes of carsickness in adults.

The fact that infancy is the most common age for the beginning of carsickness—a time when sensory impressions are merely in course of development—makes it difficult to assign a positive cause

for the existence of carsickness.

The fact that carsickness occurs during sleep tends to exclude the visual factor in carsickness. It is also noteworthy that recognition of objects is hardly developed before the sixth month. Even the power of coordinated ocular movement is lacking before the third month.

The gastric cause is negligible, because babies subject to carsickness will vomit whether food has just been given them or their stomachs are empty. The time of day or time after feeding has apparently no relation to the condition. It matters not whether the child is fed on mother's milk, water, cream, or coffee, so far as carsickness is concerned. On the other hand, babies that vomit easily from overloaded stomachs or for other reflex causes may ride on cars free from any disturbance.

Cerebral concussion, it is true, does cause vomiting, but children, subject to carsickness, suffer many severe concussions without any vomiting at all. And cerebral concussion severe enough to cause vomiting would cause more lasting effects than are apparent in carsick youngsters. The theory of cerebral concussion fails to explain the persistent sense of car motion.

The irritation of the vestibular nerve by movements of the endolymph of the semicircular canals appears to me to be the most reasonable and satisfactory explanation of the reflex causing carsickness. It is important to note that carsickness, begun during infancy, may persist throughout-adult life. There may be a gradual disappearance after puberty. The sickness may become moderate until only a slight feeling of nausea remains—or the sickness may only be induced after a gradually increasing period of car riding. There is no close relation between carsickness, sickness from swings, elevators or carrousels. Fundamentally they may be on the same basis.

Koellereutter (7) has determined that the auditory nerve reacts to irritation within a few hours

after birth. It is well known that during infancy the ears are particularly sensitive to sound. It is not unreasonable to believe that the vestibular branch is just as acute as the cochlear branch. The ear functions are the best developed in infancy, and are more important in determining equilibrium during the early period than the other special senses. Even tactile sensation is imperfect throughout the entire first year of life.

Wells (8) regards the majority of cases of vertigo as dependent upon disease of the auditory apparatus. The proximate cause of aural vertigo he places in the semicircular canals and vestibule of the labyrinth, while appreciating that actual disease of the

labyrinth need not exist.

Darnall calls attention to the vertigo and vomiting often caused in children by whirling around. The circular motion transmits its impulse to the endolymph. When the child ceases to whirl the motion of the endolymph does not cease immediately, and the child has the sensation of going round. This is a persistent sensory impression due to the unnatural disturbance of the endolymph. The sensation of persistent motion as described by children able to tell their sensations from carsickness speaks for the disturbed motion of the endolymph. Savory (II) makes this disturbance of the endolymph the real ætiological factor of seasickness.

Gray (12) says: "There can be little doubt, at any rate in mammals, that the functions of the canals and vestibule are correlated in some way with the extent and delicacy of the movements of the

head upon the trunk.'

Friedberger (9) and Fröhner describe a physiological vertigo of horses transported by boat or railroad. Hering states that seasickness is observable in dogs as well as horses. Fowls, too, are subject to carsickness. The occurrence of carsickness in these animals is naturally opposed to a psychic cause being the whole origin of seasickness and carsickness.

It is noteworthy that in the animals in whom maintenance of equilibrium during motion is most essential, as the fishes and birds, the semicircular canals are particularly well developed. Fishes, in fact, have practically merely semicircular canals. Experimental work on birds has shown that section of the semicircular canals causes the bird to sprawl

and go through forced movements.

Ménière's disease with its vertigo has long been attributed to disease of the labyrinth. The semicircular canals are recognized as the main factors in equilibration. Gowers has stated that "in nine cases out of ten in which there is definite giddiness, not epileptic in nature or obviously due to organic brain disease, it is due to a morbid state of the labyrinth or auditory nerve endings." Without going into all the anatomical and physiological details, I have come to the conclusion that carsickness is a motor neurosis due to a disturbance of equilibrium, dependent upon irritation of the vestibular nerve, originating in disturbance of the endolymph.

A few practical points have arisen in consideration of carsickness. Parents seldom say their children suffer from carsickness unless specifically asked. The vomiting of carsickness may at times suggest an overloaded stomach or the onset of an infectious disease. In adults carsickness has frequently caused a suspicion of drunkenness to fall upon its victim. Carsickness has been mistaken for appendicitis. It is most important to distinctively exclude carsickness in all cases of acute illness occurring on trains and other cars, just as one must distinguish seasickness from other sickness at sea. The condition of a carsick person may appear most serious-in fact, suggest a fatal outcome, but this does not occur. Carsickness is so common that a narration of cases would not add anything to the subject. A careful study by otologists and pathologists of intraaural conditions in children known to have carsickness might give some little light upon the true proximate cause of what is now merely termed a neurosis.

SOME IMPORTANT POINTS IN THE ANATOMY AND SURGERY OF THE PERITONÆUM.*

> By Arthur J. Wolff, M. D., Hartford, Conn., Gynæcologist to St. Francis Hospital.

In the primary phases of ontogenesis there appears between the two layers of the divided mesoderm an irregular sinuous space which represents the origin of the pleuroperitoneal cavity. primitive coeloma, at first single, is soon divided by two vertical partitions (mediastina) and a horizontal one, the diaphragm, into secondary cavities, the pleural, pericardial, and peritoneal. Thus, all the splanchnic serosoties, distinct in descriptive anatomy, are in reality contiguous diverticula of the same system, the original unity of which is demonstrated by their development.

This close embryonogenetic relationship is again to be seen in pathology, where the same general laws prevail as to the ætiology, pathological anatomy, and clinical evolution of the different varieties

of pleurisy, pericarditis, and peritonitis.

If these points are carried in mind the apparently complicated ætiology of these affections, and particularly of peritonitis, would be greatly simplified. However, if the common origin of these serous membranes explains the analogy of their morbid tendencies, the diversity of the anatomical relations which they bear to neighboring organs, produce pathological conditions entirely different. Thus. while the pleura, pericardium, and the meninges envelop viscera which are normally aseptic, the peritonæum, on the contrary, covers the most septic of all the organs of the body, the intestines.

^{*}Read before the Section in Surgery of the Hartford (Com) Medical Society, May 25, 1008.

At this place a most thin and fragile barrier, the intestinal wall, separates the most infected cavity of the economy from a membrane which is the most sensitive to infection. Thus, while the other serous membranes are the most often infected in an indirect manner from the circulatory system, the peritonæum, on the contrary, derives pathogenic agents from the most proximate sources; is infected directly by effraction, contiguity, or continuity, dependent upon the septic organs which it invests.

Amongst the unfortunate peculiarities of the peritonæum (unfortunate from the medical and surgical standpoint), is the fact that when the inoffensive saprophytes which exist within the intestines are transplanted upon it, they soon become most virulent pathogenic microbes; and between these two contrary conditions of bacterial activity there is but the minute thickness of the intestinal walls; and yet, as Wegner states, the surface of the peritonæum is so extensive as to be equal to the whole integument of the body.

Turning our attention for a moment to the anatomy of the membrane, we find that it is mostly constructed of connective tissue as a framework, superficially of a network of white fibres, while situated more deeply are to be seen large numbers of elastic fibres, which, as has been remarked by Baker, give to it its extensibility and adaptability. "No matter how much the abdomen may be distended by pregnancy or ascites, the peritonæum returns to its normal size when the distending body is removed. When the organs are displaced, the peritonæum stretches and follows them; when they return to position, it returns also, its elasticity enabling it to do this without wrinkling. Hence it occurs that the so called cavity of the peritonæum is only a virtual one, for when the organs are in a state of health, the parietal and visceral layers are closely applied to each other. In case of effusion

the cavity becomes real."

Covering the fibrillar structure of the membrane is to be observed a layer of flat endothelial cells, placed in such a maner that they are set together by their edges, not unlike mosaic work, and in certain parts, particularly upon the diaphragm, there are larger areas in which are found larger cells possessing a granular structure, which are described by

into the sac, the layers are at once separated, and

Klein as "germinating cells." Simple though the structure of the membrane appears, it is extremely rich in bloodvessels, and, owing to the cellular and connective tissue arrangement, the bloodvessels are formed in it with very great rapidity; thus, while the membrane is light gray in appearance in health, or in the inactive state, it very quickly becomes of a deep red color when attacked by inflammation. Beside the bloodvessels, the peritonæum is especially rich in lymph capillaries which ramify in great numbers all through it, thus making the cavity the most important one in the body in its relations to the lymphatic system, and explaining many of its pathological and physiological characteristics. The lymph capillaries here found in immense plexuses simply follow the rule that is found to be true in other portions of the body, that this is one of the most important functions of the connective tissues viz., to serve as a bed or

origin to the lymphatic vessels. I wish it were possible to enter more fully into the anatomical structure of the peritonæum in its relations to the lymphatic system, but I have only time to touch upon these points and to call your attention to one or two points of physiological importance, and of great interest to the surgeon.

Following Foster's description of the anatomy and physiology of the peritonæum, we may say that wherever bloodvessels go in the peritonæum, lymph spaces go too. Thus, it is to be remembered that certain parts of the blood plasma pass through the walls of the bloodvessels and become lymph in the lymph spaces. From here it is gathered into larger lymphvessels, until, at last, it finds its way into the blood current again, either into the thoracic duct which joins by a valvular opening the junction of the left jugular with the left subclavian veins, or in the smaller, less important, right lymphatic trunk with the same vessels on the right side.

Thus a constant flow of lymph is going on throughout the whole extent of the peritonæum, as in all parts of the body, from the bloodvessels through the lymphatic vessels, and back again to the blood, and in this regard it is important to remember, I, that the lymphatic vessels are richly supplied with valves, while the lymphatic capillaries are unsupplied with them; 2, the aspiration effect of the thorax, which tends to suck the lymph from the terminal trunks into the veins, and thus to maintain the lymphatic current; and 3, the effect of pressure at the periphery, which really originates in the left ventricle.

From what I have said so far, the peritoneal cavity, as well as the pleural, pericardial, and other large serous cavities, are really parts of the general lymphatic system, and the serous fluid which is at all times found in them is in reality lymph.

Another important point of interest to the surgeon in the histological structure of the peritonæum is the existence of "stomata" formed by a converging group of cells, which stomata are surrounded and guarded by a crown of granular cells. These are much more numerous in the centrum tendineum of the diaphragm. The orifices are guarded as in other places, but here they seem to have a more regular arrangement as well as a more effective function.

This portion of the diaphragm seems to be more richly supplied, too, with lymphatic vessels. Now, it is very well known that the movements of the diaphragm in breathing greatly increase and assist the flow of lymph through the stomata in this situation. and it is also well known that if a solution of Berlin blue is injected into the peritoneal cavity of a living animal, it soon enters into and injects the lymphatic vessels of the diaphragm; and the same result may be produced by injecting the coloring material into the cavity of the dead animal, and hanging it with the head downward, or even while in this position pouring the coloring fluid into the hollow of the diaphragm, and then producing movements of the diaphragm by efforts at artificial respiration. Thus bacteria and other infectious particles can find their way into the lymphatic system and into the blood stream, and to this fact is due the "postural" treatment of perturnus so highly lauded by Fowler, Kelly, and some of their followers.

Perhaps I have not sufficiently illustrated this principle by which lymph is carried back into the blood current along the regular and irregular lymphatic channels from whence it originally came, but I have only wished to recall to your minds the physiological fact that it occurs, and that this circulation is no uncertain thing; and, furthermore, that the rapidity of the current is increased by rhythmical contractions of the lymphatics themselves, which are (at least the larger ones are) distinctly provided with muscular walls.

There is a peculiar interlacing of muscular fibres above each valve, which suggests that these act after the fashion of a tiny heart, and by rhythmical systole drive on the fluid which, by the action of the valve below, collects at the spot. Some of the lower animals, as the frog and other amphibians, are actually provided with these pulsating lymph hearts. All the experiments, which I have cited, were done by injecting the fluids into the closed peritoneal cavity. But, if the cavity is opened, it will be found that the injection of the Berlin blue solution does not reach the centrum tendineum; on the contrary, a large quantity of lymph immediately begins to flow from the opening made, which carries with it the coloring material introduced, and this continues until the opening is either walled off by exudate separated from the lymph, or is closed. In other words, the current flows in the direction of the least resistance, and the amount of transudate is increased, due to the vasodilator impulses passing through the splanchnic nerves. This latter produces, of course, increased pressure in the capillaries, and results again in increased transudation.

The importance of the nerve supply in this regard will be appreciated when it is considered that parallel to the subperitoneal arterioles are distributed throughout the whole abdomen numerous sympathetic polyganglionar plexuses, and scattered here and there, in the same, may be observed numerous corpuscles of Pacini, which provide the peritonæum with a nervous supply perhaps richer than in any other portion of the body. This explains why it is that, while in the normal condition the peritonæum being almost devoid of sensibility, the slightest morbid activity suffices to render it most extremely

The peritoneal surface represents, then, a vast nervous surface, from which any powerful irritation reflects through the sympathetic nervous system upon the cardiopulmonary circulatory system and profoundly disturbs their equilibrium. We have here the explanation of the crises of asystole often observed in the beginning of a peritonitis, and also the manifestations of morbid innervation so often seen in these cases; and these, grouped together, constitute the peritoneal syndroma; as vomiting, constipation, meteorism, pain, tachycardia, alteration of the countenance, of the pulse, etc. It explains, also the ensemble of that group of nervous symptoms simulating peritonitis, described by Gabler under the name of "peritonism," which is very apt to be the cause of grave errors in both diagnosis and prog-

With these principles in view, we come, new,

to consider the peritoneal cavity from the surgical standpoint.

I do not hesitate to divide acute peritonitis into two varieties: The first, septic peritonitis, caused by pyogenic microbes, and the second, putrid peritonitis, caused by saprogenetic bacteria.

Of course, we can easily understand how one of these forms may occur during the course of the other, caused by the secondary migration of the bacteria of the intestines into a serous membrane already infected by pyogenetic microorganisms, or the ultimate predominance of septic bacteria over saprogenetic organisms in a case of mixed infection.

This division of acute peritonitis into two varieties corresponds in reality to bacteriological and clinical facts that are well known, of which the mixed form is by far the most frequent.

There is also another form of peritonitis of amicrobic origin, which one may call toxic, caused by the toxines which result from bacterial growth, or by general autointoxication without the assistance of bacteria, which is sometimes observed in Bright's disease, diabetes, etc., but, for our purposes, we may remark that every acute peritonitis we have to deal with is secondary to an infection of the peritonæum by bacteria which have gained access from without, or extrinsic infection, by intrinsic, local, direct infection, as from septic portions of the abdomen; by the general circulation, as during the course of the septicæmias, which may be called general intrinsic infection, indirect or metastatic infection.

Peritonitis which supervenes as the result of any traumatism, solution of continuity, operative or otherwise, is due to extrinsic infection. In general, one may say that by far the greater number of cases are due to extrinsic infection by the Bacillus coli communis, or the pyogenetic streptococci and staphylococci. In these cases the severity of the disease varies within the widest limits, and the poison may be so virulent as to cause death within twenty-four hours; and all that may be found at the autopsy may be a slightly reddened condition of the visceral peritonæum and a few ounces of blood stained serum in the most dependent portions of the cavity; or the disease may be accompanied with large flakes of tough lymph the thickness of chamois leather, gluing together large portions of the intestines, and pockets of pus may be seen here and there shut off from the general cavity or between the coils of the intestines shut in by lymph.

The explanation of the variation of the severity of the infectious process may very easily be found in the variability of the virulence of the organism producing it. Klecki has recently shown that the greatest variability in the virulence of Bacıllus coli communis can be produced by varying the conditions of growth in the intestines under just such circumstances as those in which the surgeon is liable to have to deal with this organism.

A simple saprophyte in the normal intestine. Klecki has demonstrated that equal quantities of Bacilli coli injected into the peritoneal cavity are much more virulent if taken from the ileum than those taken from the colon; and that the latter are much more active than that taken from the jejunum. The explanation for this may be found in the variation of the chemical reaction of the contents of the

mtestine at different heights. Klecki now made comparative investigations of cultures of Bacilli coli taken, first, from experimental strangulated hernia of the dog; second, that taken from a normal loop of intestine. He found, amongst many other characteristics of differences of virulence, that while it required a very large dose of a bouillon culture from the normal intestine to kill a guinea pig, that derived from the strangulated loop was so extremely toxic that it required but 1/6 c.c. to kill a guinea pig of the same weight when injected into the peritoneal cavity.

But Bacillus coli communis is not the only organism to be found in the intestines, and the variability of their virulence is similar to that of Bacillus coli; so that this symbiosis gives rise to a polyinfection when the organisms find their way into the perito-

neal cavity.

Another point brought out by the investigations of Klecki. He found that when he injected into the healthy peritonæum the toxines of *Bacillus coli*, an aseptic peritonitis was produced, which in a short time became transformed into a septic peritonitis by the passage of the germs through the intestinal wall into the cavity.

These experiments were repeated by Roger, and he has shown that appendicitis may be caused in the

same manner.

Arguing from the standpoint of the facts to which I have called your attention, the surgical treatment of cases of peritonitis is certainly indicated, especially when it is remembered that in general peritonitis medical treatment is of no avail. I have nothing to add to the ordinary technique: Certainly the laparotomy is simple enough. My opinion is fixed, however, on the following rule: Avoid too much irrigation in local peritonitis: use systematic and careful irrigation with large quantities of sterile water or normal saline in generalized peritonitis. My experience has led me to adopt this practice, and

I have had no cause to regret it. I cannot say that I am an advocate of the withdrawal of coil after coil of inflamed, paralyzed, and distended intestine, with the wiping of the peritonæum, as I have often seen done, and as recommended by Kelly and his followers. Such procedures may be very successful in his skilled hands, but I have never seen any marked benefit result from it in actual practice, and I have seen patients "practically disemboweled," to use Kelly's words, for the purpose of cleansing both coils of intestine and the peritoneal cavity. I never saw a patient recover after such manipulation, and I would record my vote against it in any advanced case of general peritonitis. Another vicious practice is that of tapping the intestines with a trocar or needle for the purpose of relieving the distended gut, in which I fully agree with Dr. Greig Smith, who says: "I would characterize the tapping of the bowels for tympanitis as a simple trifling with the complaint, and as dangerous trifling."

From what I have said, it may be inferred that I do not believe in the complete closure in all cases of laparotomy. When the peritoneum is wounded in ritiated, exudation occurs in direct proportion to the extent of the traumatism, and while there exists, as we have seen, great power of absorption, there

are circumstances in which the fluid cannot and will not be absorbed as rapidly as it is exuded; we must also consider and deal with the enormous quantity of sanguineous oozing which may occur from raw surfaces, and which may add in no small degree to the amount of the exudate. Thus it is imperatively necessary to avoid the collection of liquid in the pouch of Douglas, where it is extremely likely to undergo decomposition, occasionally from contamination through the intestinal coats; and if, in such cases, we feel that any doubt exists as to the transudation being likely to be greater than the absorption power of the peritoneal membrane, in cases where bleeding is apprehended, or septic or pyogenetic influences are at work, we certainly ought to drain. Another rule which has the high authority of Greig Smith, and which I have found in my experience to be true: "The older the patient is, the less active is the absorption by the peritonæum, and, therefore, the greater necessity for draining" (Greig Smith, ii, p. 126).

It being determined to drain in a given case, the

method of drainage is of grave import.

There is a certain class of cases where it is desired to set up a plastic process as soon as possible, a condition which is best obtained by placing naked gauze in the cavity. A channel is obtained, in which the affected area is soon isolated from the general cavity, and placed in the best condition for inspection and treatment without any danger of contamination.

But the gauze drain by its capillarity gives vent to a large quantity of liquid lymph, very soon becomes saturated, and in turn wetting the outer dressings, which, if properly changed, keep up the current of lymphatic action toward the drain, until it is completely walled off by plastic exudate. That the withdrawal of liquid through the drain is directly from the blood current is shown by the fact that when the drain is used the patient complains of great thirst very early. At this place I wish to call attention to the following from Martin in his monograph, After Treatment of Abdominal Section, for the purpose of expressing my dissent in as strong terms as possible: "We should insist upon total abstinence from fluids for forty-eight hours after the operation."

I consider these directions wicked and unscientific; such patients suffer cruelly with thirst. In cases where the drain is used, I allow plenty of water by the mouth, in fact, I encourage them to drink. If in bad cases, the usual large doses of saline as interstitial injections, or large quantities of water are put into the rectum, no better means can be used for cleaning out the peritoneal cavity. The extensive use of water increases the flow of the liquid through the capillary drain, and, for the reasons before stated, as the flow of lymph is reversed towards the drain, or in the direction of the least resistance, the toxines are washed out, diluted. and carried off very promptly. I have had cases in which the peritonæum was so thoroughly cleansed in this maner that the change in the condition of the patient was astonishing; while the alteration for the better in the odor and appearance of the liquid drained was remarkable. The use of large quantities of water, with good drainage, in these cases, directs the current of serous exudate towards the artificial opening, carrying with it the dead leucocytes laden with dead infectious bacteria, and, at least to a great extent, if not wholly, prevents their being carried through the cellular stomata in the diaphragm and thence into the general circulation. This is the principal reason that I urge the copious use of water and very free drainage in these cases.

The drain I use is prepared and applied in the following manner: Strips of plain gauze are made from two and one-half inches to four inches wide, and from twelve inches to fourteen inches long, according to the extent of drainage desired. gauze strips are of moderately fine mesh and of three thicknesses; it is well to have the three layers of the material sewed together at the ends. In the application of the drain, the stump of the suppurating tube, or focus of infection, is kept well in view, or secured by a proper clamp; a strip of the drain is doubled in the centre, thus making six folds of the material; this is placed behind the stump, and one folded in the same manner as the first is placed in the anterior portion of the wound, in front of the stump. One is put on either side, and we now have a "coffer dam," the spot of infection being at the bottom of the gauze dam. By separating three layers of the gauze, on each of the four sides, it will be a very simple matter if, in the judgment of the surgeon, it is necessary to pass a glass tube to the bottom of the drain for the purposes of irrigation, etc., without disturbing the walls of the wound, which in a very short time project large and very vascular granulations into the meshes of the gauze, thus completely and effectually walling off the part drained from the rest of the peritoneal cavity. presence of the gauze stimulates the growth of richly vascular granulations, which very shortly glue the outside and second layers of gauze to the whole tract of the wound.

Contrary to general opinion, I believe this to be of great advantage, as the separation of the infected spot is effectually secured by this means. This is one of the many reasons that I have for not using the "cigarette" form of drain, which I have wholly

discarded in my work.

But, with the ordinary method of gauze draining, the presence of the granulations in the meshes of the fabric is an objectionable feature to many, because it renders the removal of the pack at times very difficult, if not dangerous, while if my directions are followed, these disadvantages are completely obviated. In order to remove it, it is only necessary to separate the four sides of the "coffer dam," and, taking each side separately, count three layers from within outwards, and, grasping these with the forceps, pull gently upon them, when the gauze will strip away from the bottom towards the top of the opening, the strip when removed extending to its original length. This manipulation is repeated with the other three pieces of gauze forming the rest of the drain, and the whole track will be easily cleared from the gauze without any pain to the patient, or any injury to the tissues and granulations, and with complete absence of hæmorrhage.

I feel that the points brought out in this paper are worthy of the careful consideration of the surgeon.

, I SPRING STREET.

OXYGEN IN THE TREATMENT OF TUBERCU-LOUS PERITONITIS.*

By John A. McGlinn, A. B., M. D., Philadelphia,

Assistant Professor of Gynacology the Medicochirurgical College, Gynacologist to St. Agnes's Hospital.

Three types of tuberculous peritonitis are recognized, the ascitic form, the fibrous form, and the ulcerative form. Many plans of treatment have been advocated for this condition, and while divergent views exist as to the efficacy of the various forms, practically all authors are in accord that it is only the first type that is amenable to treatment. Thus Moynihan (1) states: "The opinion of surgeons is now almost unanimously in favor of operation in the ascitic form and against operation in the fibrous and ulcerative forms. Operations performed upon patients affected by the fibrous form of the disease are rarely productive of good results and some harm may undoubtedly be done by the attempted separation of adherent coils of bowel." The American Textbook of Surgery (2) says: "It is only the ascitic form that is amenable to surgical treatment." According to J. B. Murphy (3), "Surgery attains its best results in the dessiminated serous form. It is of comparatively limited scope in the fibrous and ulcerous varieties.

In a general way two forms of treatment are recognized, the medical and surgical. Surgical treatmen had its beginning in 1862 when Spencer Wells, mistaking the encysted dropsy of tuberculous peritonitis for an ovarian cyst, opened the abdomen. It was not until 1884 that abdominal section as a therapeutic measure was urged by König. Surgeons are now agreed thaf abdominal section is the best method of treatment in the ascitic variety. Against this view Borchgrevink, who reported two series of cases, one treated by surgical means and one entirely by medical measures, holds that the first method is inferior to the second. He also states that approximately one third of all cases recover spontaneously or under careful medical treatment.

The advantages of surgical treatment have been studied by many writers. Rörsch reports 358 cases treated surgically. Of these thirty-two patients died as the result of the operation; fifty-one patients died in eighteen months from a recurrence or an extension of the disease; 275 patients showed improve-ment, in sixty-three of these the patients were in good health and apparently free of the disease after a lapse of two years. Wunderlich reports 344 cases; eighty-one patients died as the result of operation; eighty remained well after a lapse of three years. Moynihan states that "if those patients suffering from the ascitic form are alone treated by operation the results will show a permanently good result in at least fifty to sixty per cent. of cases." Czerny reports forty to fifty per cent. of cures. Murphy says: "With proper selection of cases and especially extending the surgical procedure it is reasonable to expect seventy-five per cent. of cures."

In addition to simple laparotomy other additional methods have been advocated from time to time. In 1903 J. B. Murphy suggested the advisability of revolving the focus of infection in addition to evacuating the fluid. W. J. Mayo, who adopted the suggestion, reports that in many instances where sim-

^{*}Read before the Philadelphia Obstetrica' Society, June 1908

ple laparotomy failed, a secondary operation for the removal of the focus of infection resulted in a permanent cure. A. Döll advises the use of vioform (iodochloroxyquinoline). He conducted a series of experiments on rabbits. In sixty per cent. of the cases the process was cured; in twenty-five per cent. there was an improvement of the condition, and in sixteen per cent. no favorable action occurred. After a simple laparotomy 331/3 per cent. of the cases showed a transient improvement, and in 66% per cent. no favorable effect could be seen. There was no indication of spontaneous cure in any of the controls. The solution used was 0.5 gramme of vioform to I litre of salt solution.

Rendau advises that one part of camphor and two parts of naphthol, fused by heat to make a liquid, be spread over the peritoneal surfaces. Free irrigation of normal salt solution and dusting the surfaces with iodoform have many advocates. age has been suggested, but the danger of permanent fæcal fistula has caused it to be abandoned as a

regular procedure.

Many theories have been advanced to explain the reason of surgical cures, but none have proved satisfactory. Head asks: "Is it not possible that in a large proportion of cases of the ascitic variety section may evacuate the débris after Nature's successful contest and by relieving tension and restoring normal contact aid in the cure?" Hildebrandt and Veit believe that when the accumulated serum is evacuated suddenly it is replaced by serum having bactericidal properties. Murphy thinks that "the cure by operation is effected by the subsequent inflammatory reaction with its cell proliferation which encapsulates the foci on the serous surfaces." Gatti believes that the fluid poured out by the peritonæum after operation is antibacterial.

The foregoing statements show that by the plans of treatment now in vogue the fibrous and ulcerous forms of tuberculous peritonitis are not amenable to treatment, and at best only seventy-five per cent. of the ascitic forms can be cured. Further, that no positive reason can be given for the cure by surgical intervention, so that it is impossible to devise a scientific form of treatment. For these reasons I have the temerity to suggest a plan of treatment which has given me admirable results. In April, 1904, reasoning from a false hypothesis, I was led to try the use of oxygen in all cases coming to me for treatment. In all I have used the method in fifteen cases; of these four were the fibrous variety. In this paper I intend to report only the latter cases, reserving the ascitic type for a later report, following further investigation.

CASE I.-Mrs. K., admitted to St. Agnes's Hospital March

6, 1904.
Examination: Uterus posterior, pelvis blocked, abdomen scaphold, examination of heart and lungs negative.

Diagnosis: Pelvic peritoritis.
Operation: Median abdominal incision. On opening the abdomen the intestines and pelvic structure could not be seen, being covered with a thick layer of lymph. The parietal peritonæum was covered with small tubercles. attempt was made to separate the adhesions, but was found to be impossible. I succeeded, however, in separating the uterus from the intestines. Oxygen was introduced the peritoneal cavity for twenty minutes. A glass d age tube was placed behind the uterus and daily inflation of abdomen with oxygen practised through the tube. The patient left the hospita with a need tistula

Her physician reported two months ago: The fæcal fisrefer physician reported two months ago. The factal natural is now closed. Patient is in good health and apparently free from her old trouble. She has gained weight and is able to attend to all her household duties. She con-

and its after to at their to at their inspection duties. She considers herself perfectly well.

Case II.—Mrs. H., admitted to the Medicochirurgical Hospital January 30, 1907.

Examination: Pelvis blocked, impossible to outline any of the pelvic organs; examination of heart and lungs

Diagnosis: Pelvic peritonitis.

Operation: Median abdominal incision. On operation the intestines and pelvic structures were bound together by dense adhesions. Tubercles scattered everywhere. Oxygen was introduced into the peritoneal cavity for thirty minutes. Incision closed, no drainage.

I examined this case three months ago. The abdomen was then soft. The pelvic organs could be outlined and the uterus was freely movable. Patient was in good health. She had gained weight and considers herself cured. She was able to fill her part regularly in a one night stand the trivial examination.

theatrical organization.

Case III.—Mrs. R., admitted to St. Agnes's Hospital March 4, 1906. Examination: Pelvis blocked, uterus fixed, abdomen scaphoid, examination of heart and lungs negative. No

history of pelvic infection.

Diagnosis: Probable adhesive tuberculous peritonitis.

Operation: Median abdominal incision. The intestines and pelvic structures were densely adherent. Operative diagnosis confirmed provisional one. Oxygen was intro

duced into the perioneal cavity for thirty minutes.

I examined this case a short time ago. Patient was then apparently in good health. She had gained weight and considered herself cured. Pelvic organs could be easily outlined, uterus was freely movable.

CASE IV.-Miss H., admitted to St. Agnes's Hospital

March 6, 1907. Examination: Free fluid in the peritoneal cavity. Examination of heart, lungs, kidneys, and liver negative.

Diagnosis: Ascitic tuberculous peritonitis.

Operation confirmed diagnosis. The intestines and omentum were lifted up above the umbilicus and densely adherent. Small tubercles everywhere. Encysted fluid below the intestines. The fluid was removed and oxygen introduced for thirty minutes. After operation she had a slight return of the fluid.

Two weeks ago her doctor reported as follows: Fluid disappeared shortly after her arrival home. There has been no return of the condition. She has gained weight

and is apparently in good health.

I use the method as follows: The water bottle of the oxygen apparatus is sterilized and filled with sterile water. The tube leading from the bottle and the rubber tip are sterilized. The tip is covered with several thicknesses of sterile gauze. The oxygen is introduced through the abdominal incision until the abdomen becomes inflated. The incision is now closed with gauze, and the oxygen is allowed to remain for several minutes. The gas is then allowed to escape, and the peritoneal cavity is filled again and again.

THE ÆTIOLOGY AND TREATMENT OF ECZEMA. BY ZAMA FELDSTEIN, M. D.,

New York,

Attending Physician in the Department of General Medicine it the Dennit Dispensary; Attending Physician at the Northwester i Dispensary

In recent years most extraordinary progress and most wonderful advancement in the treatment of disease have been made in medicine. This is particularly true of cutaneous diseases, since there always has existed such diversity of opinion as to their causation and mode of treatment. Eczema is conceded to be one of the most obstinate of all diseases of the skin; it certainly is by far the most frequent, and hence practically the most important of all cutaneous affections. Erasmus Wilson, Malcolm Morris, Bulkley, and McCall Anderson agree that eczema forms one third of all skin diseases that come under treatment.

The causation of eczema has for centuries been a source of mental anxiety and controversy amongst the members of the medical profession, arising from a misunderstanding of its inherent nature, cause, and progress. The general impression until quite recently has been that eczema is produced by either local irritation or some constitutional impairments. We have been told that eczema may be caused by a disturbance in the gastrointestinal canal, producing an infection, or that it may be produced by gouty states, or some other indefinite general disturbance.

Unna, with his conception of the parasitic origin of eczema, has revolutionized ancient dermatology. He distinguishes twenty-three different types of cocci.

Eminent dermatologists of to-day have proved beyond doubt that eczema is primarily caused by the direct action on the skin of microorganisms or their toxic products. In making cultures they have found cocci of the type of the Staphylococcus pyogenes albus, Staphylococcus pyogenes aureus, and the Streptococcus pyogenes. The local infectivity and chronicity of eczema, the purulent manifestations which occur so easily, are no doubt ascribable to the presence of these microorganisms.

For its production two conditions at least are necessary: Firstly, a predisposition or special irritability of the skin; secondly, an exciting influence which brings this irritability into action. Cases of simple seborrhoea or dermatitis are frequently transformed into an eczema, and there can be little doubt that this is caused by the action of microorganisms

and the toxines which they secrete.

I hold that eczema is a parasitic disease, and the only thing necessary to produce an eczema is the congestion of the skin, which may be produced by constitutional ailment or defect, or by outside influences, such as cold or chill, and further I am of the opinion that the parasite, having been once called into activity, as it were, the primary cause can be cured, but the effect, i. e., the parasite, remains until destroyed by a parasiticide sufficiently penetrating to establish contact, and sufficiently stimulating to restore the skin to its natural activity. Neisser has summed up his belief as to the ætiology of eczema in the formula, "No eczema without micrococci."

Dermatologists the world over are gradually accepting the parasitic theory of eczema, because it is impossible to believe that parasites known to possess certain pathogenic properties can be present in every case of eczema, and in such numbers as they have been proved to be by most competent observers, without having a decided effect on the character and severity of the disease.

In the treatment of eczema we find that the majority of remedies used are of an antiseptic nature. That it is purely a parasitic disease, produced by

some local toxic or microbic irritant, and can only be treated locally, is proved by the fact that such drugs as resorcin, sulphur, ichthyol, salicylic acid, and creolin, all of which are well known antiseptics, are constantly being used in the external treatment of eczema. Being a parasitic disease, the constitution, when involved at all, plays but a secondary part in the process. There is no specific for eczema. In every case the great aim should be to cure the lesion as rapidly and as thoroughly as possible.

The local treatment by the application of a penetrating, stimulating parasiticide is usually all that is necessary to complete a cure, but where the constitution is involved, appropriate constitutional remedies must be employed. I do not want to deprecate the constitutional treatment, but the latter treatment is only useful as an adjunct, and that is why I assert that, where the constitutional treatment is indicated, it is only necessary as an adjunct to the local treatment. It seems to me that it is a fallacy to look upon eczema as a provision of Nature for the elimination of toxic principals resulting from constitutional and often hereditary disorders of nutrition.

Tar and its derivatives and mercurials, which penetrate the skin, are the most active remedies, because they are parasiticides. Carbolic acid, aluminum acetate, potassium permanganate, and thymol are other antiseptics which have proved to be of great value.

In the treatment of eczema the following aims are to be constantly kept in view: 1. Destroy microorganisms. 2. Protect the inflamed surface from further microbic invasion. 3. Regulate the strength of the remedy employed to the tolerance of the patient's skin. 4. Soothe when acute. 5. Stimulate when chronic.

In using parasiticides it is always essential to carefully regulate the strength of the remedy in accordance with the sensitiveness of the patient's skin and the severity of the disease. The simplest procedures are often the most successful. It is always good to commence with the very mildest possible remedies, and then gradually to increase the strength of the remedies employed. Diet has only an indirect influence. Patients should take such food as they find most suitable to their digestive powers. When, however, some constitutional ailment coexists with the eczema, such as gout. diabetes, etc., then, and then only, is special dieting

Therapentical Aotes.

The Treatment of Pulmonary Hæmorrhage.—In the Journal of the American Medical Association for July 11, 1908, it is noted that the question of the proper treatment of this condition or emergency constantly recurs, and it seems to be necessary to reiterate the advice that the blood pressure should not be raised by such drugs as ergot, digitalis, etc., with the idea of stopping the bleeding. All hæmorrhage from the lungs, unless it is from an aneurysm, tends to stop, but the proper treatment for the condition is to lower the blood pressure with nitrites.

At a meeting of the American Therapeutical Society. in Philadelphia, Dr. Lawrence F. Flick stated in a paper which he read on the treatment of tuberculosis that whenever he found a pulmonary second sound accentuated or increased in force he put the patient immediately on nitroglycerin, and in this way he believed he minimized the danger and frequency of hæmorrhages.

Dr. Albert P. Francine, in the Pennsylvania Medical Journal, January, 1908, very ably discusses the treatment of hæmoptysis. He uses the official spiritus glycerylis nitratis in one minim doses immediately on the occurrence of pulmonary hæmorrhage, and repeats the dose at two hour intervals. or oftener in severe cases, and in severe hæmorrhage has given a minim (two drops) every half hour for four or five doses. If the hæmorrhage is alarming and the patient is nervous, he administers 14 grain of morphine with 1/150 grain of atropine, hypodermically. It is often advisable to use morphine to quiet the patient's nervousness in pulmonary hæmorrhage, but 1/8 grain, or one half the above, is almost invariably sufficient. If this small dose is administered atropine is then not needed to stimulate the respiratory centre or to prevent the overaction of the morphine, and, as it is a vasoconstrictor, it is best not to administer it.

Francine lays down the usual rules for the immediate treatment of this condition, viz., absolute rest. flat on the back with one or two pillows, as the patient prefers. Talking must be forbidden. No warm drinks, alcoholic or otherwise, are allowed, and no solid food is permitted. Cracked ice in small amounts may be given to dissolve in the mouth, and perhaps a light weight, flat ice bag may be put over the heart to quiet its overaction. Similar ice bags may be placed over the site of the bleeding, if deemed advisable. Strapping the chest on the affected side and limiting its mobility is sometimes of service, and Francine speaks of the occasional necessity of bandaging the extremities so as to retain the blood in them until the hæmorrhage ceases. If this is done the bandages should be loosened gradually and not all at once, so that too much blood will not be thrown into the lungs at one time.

It is probably rarely advisable in pulmonary hæmorrhage to do transfusion with blood, salt solution, or any other solution, or even to do hypodermoclysis.

Francine thinks that after the arrest of the harmorrhage the patient should be kept in bed at least ten days. This, of course, depends on the amount of the hæmorrhage and its cause.

Francine advises the usual treatment to prevent hæmorrhage, viz., the administration of calcium chloride or lactate, and the feeding of gelatin, as a jelly. He cautions against using large doses of calcium chloride too long, as it tends, in large doses. to interfere with the coagulation of the blood. This aution was concurred in by Dr. Meyer Solis-Cohen, of Philadelphia, in discussing Francine's paper; he stated that Dr. A. E. Wright, of London, has shown that when large doses of calcium chloride are given for some period, the coagulation of the blood is interfered with. Therefore, after two or three days of the ordinary dose of calcium chloride, it is well to suspend its administration.

The following methods of administering the calcium salts are recommended:

Granulated acacia. 3iii;
Cinnamon water, 3iii;
M. et Sig.: A teaspoonful, in plenty of water, every three

Calcium chloride, in spite of the mucilage, is irritant to the stomach, and sooner or later causes considerable irritation, consequently the following tasteless preparation is the better:

Fac chartulas 20.

Sig.: One powder, with water, every three hours.

When Sodium Bicarbonate Is Best Administered.—In a note on the action of sodium bicarbonate on the gastric contents cited by the Pharmoceutical Journal from Bulletin Commercial, it is stated that, if the stimulating effect on the gastric secreting organs is required, sodium bicarbonate should be given before meals. The first effect is to render alkaline the gastric contents; this is gradually neutralized and the secretion of acid is stimulated until ultimately the normal acidity of the gastric juice is exceeded. If the drug is administered to an over acid subject during the process of digestion, the food may pass out of the stomach before the normal acidity has been restored, so that the beneficial action would be lost. Some time should he allowed to elapse, therefore, between the administration of the dose and the ingestion of food. This period varies with different quantities of bicarbonate. The maximum of acidity is generally attained in two hours after a dose of eight grains; in three after one of sixteen grains. Small doses may therefore be given at meal times, but larger quantities should be given about an hour before meals. The dose itself must be varied according to the case; in some instances as much as eighty grains will be required, given an hour before meals to attain the maximum of acidity, but this quantity is much too great for patients with accentuated hypoacidity; for these eight grains may prove sufficient. In the case of excess of acidity larger doses should be given some time after meals so that the chyme may leave the stomach before the acid condition has been reestablished. Sodium bicarbonate is found to relieve the pain of tardy digestion in a very effective manner in cases of deficiency of acid.

Liniment for the Breast.-A correspondent of The Prescriber for August, 1908, sends the following prescription for the dispersion of a benign tumor in the external breast:

Soap liniment, ... ad. 5ii.

M. et Sig.: Shake the bottle and then rub breast between nipple and base of mamma, backwards and forwards, awice daily. Cover with flannel or Gamgee tissue.

Catarrhal Conjunctivitis. The application of a vellow oxide of mercury ointment of the following composition has given good results in the treatment of catarrhal conjunctivitis in the hands of M. Mallet (Bulletin général de thérapeutique, June 15, 1908):

Gentle massage of the cyclids is to be recommended in association with this treatment.

NEW YORK, SATURDAY, AUGUST 22, 1008.

INEQUALITY OF THE TWO BREASTS.

M. Variot and M. Lassablière have been investigating an anomaly which, so far as we know, has not often if at all engaged the attention of physicians, that of a difference in the size of the two breasts. They reported, at a recent meeting of the French Academy of Sciences (Semaine médicale, August 5th) that they had examined the breasts of 550 women from the country who sought employment as wet nurses in a Paris hospital for children. They found inequality of the two breasts in size to be by no means exceptional, but rather the rule, during lactation; in fact, in only twenty-four per cent. of the women examined did they find the two breasts of the same size. Generally it was the left breast that was the larger, 281 times, while in only 138 instances did the right breast exceed its fellow in size.

As the efficiency of a secreting organ is proportionate to its size, other things being equal, it is not astonishing that they found that more milk was secreted by the larger breast than by the other one. They milked forty women dry, and the difference in the amounts of milk obtained from the large and from the small breasts ranged from 40 to 335 cubic centimetres (approximately, ten fluid drachms to ten fluid ounces and a half). But it does not seem so easy to account for differences in the quality of the milk from the two breasts. The smaller gland, they find, yields milk richer in fat and casein, but somewhat defective in sugar. As a conse-

quence, the baby is inclined to avoid the little breast, and that leads to a still greater reduction of its size, so that sometimes it undergoes such a degree of atrophy that the nurse is left with only one available breast.

Our authors state that this inequality of the breasts as regards size exists in young girls as well as in nursing women. This fact they set down as probably due to heredity, but they add that in the nurses examined by them the difference in the size of the breasts was manifestly due to the greater frequency with which, for reasons of convenience, the women gave the left breast to the child. Now, if the anomaly which they have investigated is really hereditary, why should they endeavor to account for it as something acquired? At all events, it ought to be corrected, they remark, and they think that the best way to secure that result is to insist on giving the infant the lesser breast.

MERCURY IN TUBERCULOUS DISEASE.

Surgeon Barton Lisle Wright, of the navy, contributes to the July number of the United States Naval Medical Bulletin a second article on this subject. It is preceded by an extract from Medical Inspector C. T. Hibbett's letter of transmittal in which he says: "We are almost convinced that mercury, judiciously used, is a specific in the treatment of tuberculosis in all its forms." In the article itself Surgeon Wright declares that he is convinced to that effect, the only question left to be decided being that of how long it will take to effect a cure. He fortifies his opinion with sufficiently detailed histories of twelve cases and argues very effectively that it is not merely syphilitic lesions that he is curing at New Fort Lyon. He properly insists that all known agencies for the cure of the disease must be kept at work during the administration of the mercurial course. He does well to keep the subject before the profession, for the sooner a consensus is arrived at in regard to it the better. We expect to publish still another of Surgeon Wright's articles on the mercurial treatment of tuberculous disease in our next issue.

AN INDETERMINATE NERVOUS AFFECTION.

No wise physician ever underrates the importance of "nervousness," unless indeed he believes it to be assumed or purposely magnified. The complicated mechanism of the nervous system is easily thrown out of gear, and all its derangements, however trivial they may appear, are terribly real to the person in whom they show themselves. Most of them, if not all, depend upon some actual ab-

normity, though it is often extremely difficult to ascertain its situation and its nature. A very painstaking and praiseworthy attempt to detect the pathology in two cases has been made by Dr. Hamilton Graham Langwill, physician to the Leith Hospital. Dr. Langwill set forth his investigation of these cases before the July meeting of the Edinburgh Medicochirurgical Society in a paper entitled Note on the Treatment of a Type of So Called "Fainting Attack," which appears in the August number of the Edinburgh Medical Journal.

Dr. Langwill's first patient, a woman, forty-eight years old, had been under his care most of the time for twelve years. Her attacks were usually ascribed to her heart, but there was never any dyspnœa, palpitation, cardiac murmur, or irregularity of the pulse. Nevertheless, she was treated with strychnine and strophanthus, but on an occasion when she was more than usually distressed with what she called "queer feelings" and "fainting attacks" it is recorded that "her pulse had not improved as on former occasions" under the use of these drugsso there must have been some abnormity of the pulse. During the night following this observation Dr. Langwill was called in haste to see her, as she was thought to be dying in one of her attacks. He found her extremely pale, with a pulse rapid and of remarkably small volume, unable to speak, but acutely conscious of her surroundings. The paroxysm was rapidly overcome by a subcutaneous injection of adrenalin. Dr. Langwill gives the following additional data concerning the phenomena of the attacks:

They begin, she says, with a sudden feeling coming over her "as if something dreadful was going to happen"; then follows a strange feeling of inward shaking and "sinking" in the umbilical region, unaccompanied by any pain or dyspnæa, but with an overpowering sensation as if she was dying, consciousness, however, being always intensely alert, though the power of speaking or even moving is lost.

1. It is interesting to note that she has by experience found that she often goes to sleep most easily in the prone position.

2. Another interesting condition, she states, occurs frequently if she is awakened suddenly, viz., a feeling as if she "woke up in detachments"—her consciousness wakes quite brisk and vivid, but the power of speaking and moving distinctly lags behind for an appreciable period.

The second patient, a woman, thirty-eight years old, had almost precisely the same symptoms. She found relief by assuming the knee elbow posture, "so as to benefit by the flushing of the bloodvessels in the extremities which results on relaxing the 'tourniquet' action of this 'forced flexion.'" Immediately after a confinement she imputed her alleviation to the pressure of the obstetrical binder. In both cases the blood pressure was found to be very low, and both patients derived considerable benefit from wearing an abdominal pad and bandage. Dr.

Langwill suggests that the true explanation of these attacks is a rapid withdrawal into the splanchnic "venous pool" of a large amount of blood owing to the dilatation of the arterioles in this area. However that may be, the exciting cause is sometimes apparently psychic, for we know of a case, that of a man now past middle age, in which the paroxysms, to which he has been subject for more than twenty-five years, invariably come on under circumstances of constraint, as at the theatre, in church, or at a funeral, where the man has an oppressive consciousness of an unusual need of decorous behavior. In his case the dread is, not of impending death, but of impending loss of consciousness. We think that these attacks would usually be called "spells" by the laity in this country.

THE BLOOD IN ANIMALS WITH EXPERI-MENTAL TRYPANOSOMIASIS.

One of the characteristic features of the blood in cases of infection with protozoan parasites is the increase in the large uninuclear leucocytes, which is seen in its most striking form in malarial disease. In the few cases of human trypanosomiasis in which blood studies have been made, this increase has been observed. Yakimoff (Archives des sciences biologiques, xiii, 3) has contributed a systematic study of the changes in the blood accompanying trypanosome infection. He has employed Trypanosoma Brucei and Trypanosoma equinum, inoculating them into nine white mice, four white, mottled, and gray rats, ten guinea pigs, five dogs, and two foxes. The work was designed to determine the quantitative and qualitative changes of the erythrocytes and the leucocytes, the changes in the hæmoglobin percentage, the number of trypanosomes in a cubic millimetre of blood and its relation to the number of erythrocytes in the same quantity of blood, the chemical alterations of the blood, and its changes in specific gravity.

The author found that there was oligocythæmia in animals infected with the trypanosomes under consideration. The reduction varied from ten to sixty-seven per cent. in the various animals experimented with. There was, however, no poikilocytosis or any change in the tinctorial characteristics of the erythrocytes. There was also oligochromæmia of varying intensity. In some of the animals the color index was high; in others it was less than one. The author concluded that there was no reason to attribute the reduction in the hæmoglobin percentage to the destruction of the erythrocytes, because neither the color of the blood serum nor that of the urine indicated a solution of the hæmoglobin.

The infection was followed by a leucocytosis,

which reached its maximum on the third day, to be followed by a diminution in the number of these cells, which persisted until the death of the animal. The leucocytosis was due to an increase in the absolute and relative numbers of the polymorphonuclear cells. These cells showed, first, a primary increase; second, a diminution; and, third, a secondary increase. The lymphocytes were decreased in number and the large uninuclears played no part in the reaction.

The number of trypanosomes in a cubic millimetre of blood varied from a maximum of 5,280,000, in one of the mice, to 27,219, in one of the dogs, when the infecting organism was Trypanosoma Brucei. On the other hand, when Trypanosoma equinum was employed, the maximum number of parasites found in a cubic millimetre of blood was 792,000, in one of the mice, and the minimum was 10,416, in one of the dogs. Trypanosomes appeared in the blood between the second and the ninth day after the infection, and death occurred between the third and the twenty-first day. In the majority of cases the maximum number of trypanosomes were found in the blood just before death. The duration of the disease appeared to be due to the development of the trypanosomes; when these parasites reached a certain number the animal died.

The author supposes that the trypanosomes produce a substance which is positively chemotactic for the polymorphonuclear leucocytes, and that they elaborate a substance which produces fever even before the organisms can be detected in the peripheral blood by microscopical examination. Further, he believes that the parasites generate an acid which reduces the alkalinity of the blood. The cause of the symptoms of the infection and of the death of the animal is considered to be partly the morphological lesions of the organs or abnormal function of the organs, and partly intoxication with toxines or a diminution of the alkalinity of the blood.

There are other interesting questions discussed in the paper, which is concluded by a division of the disease produced by the infection with trypanosomes into three stages: First, the period from infection to the appearance of trypanosomes in the peripheral blood, characterized by an increase in the total number of the leucocytes, an increase of the polymorphonuclear neutrophiles, and a diminution of the percentage of the lymphocytes. Second, the period from the appearance of trypanosomes in the blood up to the point of death, characterized by a diminution of the total number of leucocytes, a diminution of the polymorphonuclear neutrophiles, and an increase in the percentage of lymphocytes. Third, the period of fatal termination, characterized by an increase of the total number of leucocytes, an increase of the polymorphonuclear neutrophiles, and oscillations in the percentage of the lymphocytes and their consecutive diminution.

365

THE AMERICAN HOSPITAL ASSOCIATION.

The tenth annual conference of this association, which is to be held in Toronto on September 29th and 30th and October 1st and 2d, promises to be one of great interest, for the programme includes the titles of many papers on topics of importance in connection with hospital construction and management. The organization is not a medical association; its active members are members of hospital governing boards and executive heads of hospitals, and its associate members are "executive officers of hospitals next in authority below the superintendent." Nevertheless, such subjects as will be discussed at the Toronto meeting are always of interest to medical men, and the association has indeed a fair proportion of medical members. The president is Dr. S. S. Goldwater, of Mt. Sinai Hospital, New York. The conference will be held in the King Edward Hotel.

VAGRANT DOGS IN NEW YORK.

We hope that the Health Department of New York will not relax its efforts to rid the city of vagrant dogs. The danger from rabies is very great at times, and it seems to be considerable at the present time, though it has nothing to do with the "dog days," for the disease may be as prevalent in winter as at any other time. It was well to initiate the movement during the hot weather, however, because the dog day tradition probably secures for it greater popular support than it would be easy to obtain at other times. We doubt if the method adopted by the department is appreciably more cruel than the impounding to which dogs have been subjected here in times past, and there is no injustice done to the owners of the dogs, for they know well enough that they can secure immunity for them by using the muzzle or the leash. It should be borne in mind that the danger of spreading rabies is not the only reason for attempting to rid the streets of stray dogs; they are a nuisance from all points of view.

SHARP CURVES IN STREET RAILWAYS.

Some of the new street cars in New York are exceedingly long, but the wheels are situated at a considerable distance from the ends of the car, too near its centre perhaps in some instances. It follows from this arrangement that when a car of such

construction is forced over a sharp curve in the track, as at the confluence of Broadway and Park Row and in Forty-second Street and Fourth and Madison Avenues, the ends of the car overhang the outer rail of the curve to a very great distance, thus subjecting unwary pedestrians to considerable danger of being knocked down and seriously injured. It may be impracticable to alter the situation of the wheels, but it has been suggested that some stationary protective or warning device should be adopted, such as a brass outline in the pavement to indicate the limit within which it is unsafe to stand when a car is approaching. The suggestion seems to us commendable. The brass line, it is thought, would probably arrest attention and its meaning be readily understood, and it would not obstruct traffic.

Aews Items.

Personal.—Dr. Warren Royer, of Trappe, Pa., who is the oldest practising physician in Pennsylvania, celebrated his eighty-eighth birthday anniversary on August 4th. Dr. Royer was born in Trappe in 1820. He graduated from Princeton in the class of 1842, and received the degree of doctor of medicine from the University of Pennsylvania in 1845. In the same year he settled in his native town, where he has continued practising for sixty-three years.

Dr. Samuel D. Shull, of Chambersburg, has been appointed resident physician at the Frankfort Hospital, Philadelphia.

Dr. Eric Carl Beck, of New York, son of Dr. Carl Beck, professor of surgery at the Postgraduate and St. Mark's Hospital, is in the Mt. Vernon Hospital, N. Y., suffering from injuries received while alighting from a train at the Pelham station of the New Haven Railway. Dr. Beck missed his footing and fell, his head striking a railroad tie. The condition of Dr. Beck is said to be improving.

French Surgical Congress.—The twenty-first French Surgical Congress will convene at Paris, October 5, 1908.

Oswego Hospital, Oswego, New York.—A maternity ward has been established in connection with the Oswego Hospital.

Atlantic City Hospital.—The opening of the Atlantic Municipal Hospital for Contagious Diseases will take place during the month of September. The hospital consists of a series of buildings covering a city block.

Fifth Pan American Medical Congress.—The fifth congress of the Pan American Medical Association, which opened on August 6th, ended August 13th. The next congress will be held in Lima, Peru, August, 1911.

Plague Epidemic in India.—The plague mortality in India is at present slightly decreasing, but about two million five hundred thousand people have perished since the beginning of the epidemic. Thirty thousand cases are still occurring weekly, ninety per cent. of which are fatal.

Baltimore Medical College.—The Baltimore Medical College has received permission to erect a new building at 851 North Howard Street. The cost of the building will be \$22,000, and on the ground floor will be a lecture hall, with class rooms above.

French Medical Association.—The second annual meeting of the French Medical Association met at Lille, on June 25, 1908, with about one thousand five hundred members in attendance, representing over seven thousand five hundred practitioners.

Civil Service Examination for the State and County Service.—The State Civil Service Commission of New York will hold examinations on September 5, 1908. Among the positions is one for assistant physician at the Rome State Custodial Asylum, \$600 to \$900 and maintenance. The last day for filing applications is August 20th

Remodelling of the Vanderbilt Clinic.—The four story building of the Vanderbilt Clinic of the College of Physicians and Surgeons, of New York, which is located at Sixtieth Street and Amsterdam Avenue, is to be remodelled and will be used as a dispensary in the future.

Cholera in St. Petersburg, Russia,—The Department of Health of the Russian capital has declared officially that the city of St. Petersburg is threatened with a cholera epidemic. The authorities are making special efforts to quarantine new arrivals and to inspect foodstuffs.

German Deaconess Hospital at Cincinnati, Ohio.—Mr. E. H. Huenefeld presented to the trustees of the hospital the beautiful Scarlet Oaks Cottage at Cincinnati. The mansion is to be an annex to the Bethesda Hospital, and is to be equipped for convalescents principally.

Responsibility in the Death of Dr. Carlton Flint.— The coroner's jury which investigated the death of Dr. Carlton Flint at Seabright, N. J., rendered a verdict holding responsible both the owner and the chauffeur of the automobile by which the doctor was fatally injured.

National Association of Negro Medical Men.—The association, which has in its membership physicians, denists, and pharmacists, will hold its tenth annual session on August 24th to August 26th, at Brooklyn, N. Y. A big banquet and reception have been planned for August 25th.

New Orleans, Louisiana, Statement of Mortality for the Month of July, 1908.—The official report of the Board of Health of the City of New Orleans gives the death rate for one thousand per annum for the month of July as 13.63 whites; 24.09 colored; total whites and colored, 16.68.

St. Louis University School of Medicine.—Warren P. Elmer and William Engelbach have been appointed assistant professors of medicine; William W. Graves, assistant professor of nervous diseases; M. G. Seelig, assistant professor of pathology; James M. Wilson, associate professor of embryology.

New Infirmary for Chicago.—Plans have been approved for the first of the group of buildings to be erected on the Cook County Hospital grounds at Lincoln and Polk streets. It is estimated to cost about \$2,000,000, and will be a modern structure for the care of those in advanced stages of disease.

Buffalo Good Samaritan Free Dispensary.—Incorporation papers were filed in the county clerk's office by the Buffalo Good Samaritan Free Dispensary, signed by the directors, Grover W. Wende, Nelson G. Russell, Samuel B. Botsford, Walter S. Goodale, Thomas B. Carpenter, and James E. King.

Wheeling Medical Library Association.—A medical library association has been founded at Wheeling, W. Va. The authorized capital stock is \$10,000 and the incorporators are Frank L. Hupp, Andrew Wilson, William McLain, C. A. Wingerter. W. S. Fulton, M. Gaydosh, J. Schwinn. C. M. Truschel, H. E. Cesterling, and John L. Dukey, all of Wheeling.

Trained Nurses of the District of Columbia.—According to a report submitted to the commissioners of the District of Columbia by the examining nurses' board for the year ended June 30th, the applications of seventy-eight graduate nurses were approved without examination, while twenty-nine graduate nurses had to undergo an examination.

Women Nurses for the Navy.—Orders have been prepared at the Navy Department of the United States for the organization of a corps of female nurses to correspond with the female nurse corps of the army. This corps of female nurses is to serve in various naval hospitals and is to consist of fifty nurses. The nursing on ships of war is to be left to the regular stewards.

Chicago Hospital Obtains Land.—The Memorial Association has leased the land and building for the Iroquois Memorial Emergency Hospital at 87 Market Street, for the sum of \$45,000, for ninety-nine years. The hospital will be under the management of the city. It is expected that another emergency hospital will be established near the stock yards by the association.

Tuberculosis Exhibits.—The tuberculosis exhibits shown in several cities of the State of New York during last winter will be demonstrated at thirty-five fairs this

summer. The State Health Department and the State Charities Aid Association have charge of the exhibits. Several of these exhibits will be combined and shown at the State fair which will be held at Syracuse, September 14th to 19th.

Building for Physicians, Denver, Colorado.—A six story fireproof steel building will be erected at the corner of Sixteenth Street and Court Place, at Denver. The new structure is to be given over entirely to the medical pro-fession. A special feature of the building will be a fully equipped operating room.

Annual Meeting of the Crow River Valley Association.—The sixty-first meeting of the Crow River Valley Medical Society was held at the Pilon Hospital in Paynesville, Minn., on August 14, 1908, members being present from Minneapolis, Litchfield, St. Cloud, Sauk Center, Eden Valley, and other points on the Soo line.

The Alleghany Valley Medical Society.—The Alleghany Valley Medical Society at a recent meeting at Cheswick, Fa., elected the following officers: President, Dr. W. A. Arnold, Tarentum; first vice president, Dr. W. A. Arnold, Tarentum; first vice president, Dr. W. P. McCullough, Cheswick; second vice president. Dr. R. E. McConnell, Parnassus; treasurer, Dr. A. F. Kaufman, New Kensington; secretary, Dr. W. T. Hall, Tarentum.

Death of Dr. Charles E. Parish .- Dr. Charles E Parish, president of the Otsego County Medical Society, died, August 15th, of Bright's disease, at the age of fiftythree years. His funeral was largely attended by the medical profession, the board of supervisors, of which he was a member, and the Masonic fraternity. Dr. Parish has prac-tised almost his entire medical life in Maryland, N. Y. He was the only physician in the place, yet few larger places have been better served. He was a broad man in every sense, beloved by his patients and his acquaintances.

Caroline Rest Club for Social Workers.—This club was opened at Hartsdale, N. Y., on July 25th by the New York Association for Improving the Condition of the Poor. The opening of the club has been made possible by the about an hour from New York and three minutes from the Hartsdale station. At present it consists of a three story colonial building, surrounded by a broad veranda. The entire first floor is taken up by a large living room. On the second floor are separate bedrooms, while the third floor is given up to a large dormitory. The house will accommodate thirty guests.

The Health of the Canal Zone.—During the month of June, 1908, the population of the Canal Zone, including the cities of Colon and Panama, was 120,510. 293 deaths among this population, corresponding to an annual death rate of 29.17 per 1,000. There were 3 deaths from typhoid fever; 4 from astivoautumnal malaria; 29 from clinical malaria; I from hæmoglobinuric fever; 2 from amœbic dysentery; 13 from clinical dysentery; 3 from beriberi; 3 from purulent infection and septicæmia; 2 from rabies; 39 from pullmonary tuberculosis; 2 from other forms of tuberculosis; 3 from acute articular rheumatism; 3 from tetanus; 4 from bronchopneumonia; 16 from pneumonia; 35 from diarrhœa and enteritis under two years of age; 6 from diarrhœa and enteritis two years of age and over; and I from puerperal fever.

Infectious Diseases in New York:

We are indebted to the Bureau of Records of the Department of Health for the following statement of new cases and deaths reported for the two weeks ending August

| | Aug. 8 | | \ttg, 15 | |
|--------------------------|--------|---------|----------|---------|
| | Cases. | Deaths. | Cases. | Deaths. |
| Tuberculosis pulmonalis | | 137 | 143 | 100 |

Charitable Bequests .- The will of Dr. John Ordronaux, of Mineola, who left a fortune of \$2,757,000, includes \$6.000 to the Mary Hitchcock Memorial Hospital; and \$6.000 to the Morton Hospital, Taunton, Mass.

By the will of the late Dautel F Millerick, the following

hospitals are beneficiaries: St. Mary's Infant Asylum, Dorchester; House of the Good Shepherd, and the Carney

By the will of Mary E. Abbott, the West Philadelphia Hospital for Women becomes a contingent legatee to the extent of \$5,000 for the endowment of the Mary E. Abbott extent of \$5,000 for the endowment of the Mary E. Abbott free bed, and \$150 for linen, bedding, etc. In case the West Philadelphia Hospital for Women is not in existence at the time that this bequest becomes available it is to go to the Episcopal Hospital of Philadelphia. By the will of Senator William B. Allison, the Finley Hospital, of Dubuque, Ia., receives \$1,000. By the will of Miss Annie Van Read, of Reading, Pa., the Medico Chirurgical Hospital of Philadelphia receives \$6,500.

Joint Meeting of the Medical Societies of Frederick and Washington Counties, Maryland.—The first joint meeting of the medical societies of Frederick and Washington Counties, Maryland, will be held at Bradlock Heights, on August 26, 1908. The following papers will be read: A Message to Western Maryland, by Dr. B. W. Goldsborough; State Care of the Insane, by Dr. A. P. Herring; Prevention of Typhoid Fever, by Dr. C. W. G. Rohrer; When is Rheumatism not Rheumatism?—The Passing of the Term Rheumatism in the Light of the Newer Pathology, by Dr. C. W. R. Crum; Parasites, by Dr. Tracy E. Bishop; Medicine in the Tropics, by Dr. T. A. Poole; Chemical Use of Medical Remedies of Unknown Composition, by Dr. D. C. R. Miller; Nobless Oblige, by Dr. V. M. Reichard; Sunset in Greece, by Dr. S. M. Davis. meeting of the medical societies of Frederick and W S. M. Davis.

Syracuse University.—The following changes have been made in the faculty of the College of Medicine, Syracuse University: Frank P. Knowlton, associate professor of physiology, has been made professor of physiology; H. S Steensland, associate professor of pathology and bacteriology, has been made professor of pathology and bacteriology; H. D. Senior, associate professor of anatomy, has been made professor of anatomy; Ernest N. Pattee, professor of chemistry in the College of Liberal Arts, has been made a member of the faculty of the College of Medical Physical Management Professor of College of Medical Physical Management Professor of College of Medical Physical Management Professor Office Prof ocen induce a memoer of the faculty of the College of Medi-cine; Richard H. Hutchings, medical superintendent of St. Lawrence State Hospital, Ogdensburg, New York, has been appointed lecturer on psychiatry; Ralph R. Fitch, of Rochester, New York, has been appointed lecturer on orthopa-dics; Charles V. Morrill, recently assistant in zoology in Columbia University, New York, has been appointed lec-turer on histology and embryology.

Mortality Statistics of New Jersey.—During the month ending July 15, 1908, there were reported to the Bureau of Vital Statistics of the State of New Jersey 2,589 deaths from all causes, as compared with an average of 3.030 deaths for the previous twelve months. Of the total number of deaths, 607 were of children under one year of age, and 668 were of persons over sixty years of age. The principal causes of death were: Typhoid fever, 20; measles, 21; scarlet fever, 36; whooping cough, 22; diphtheria, 36; maiarial fever, 1; pulmonary tuberculosis, 265; tuberculosis, other than that of the lungs, 49; cancer, 130; cerebrospinal meningitis, 31; diseases of the nervous system, 315; diseases of the circulatory system, 265; diseases of respiratory system (pneumonia and tuberculosis excepted) 117; pneumonia, 123; infantile diarrhœa, 202; diseases of digestive system (infantile diarrhœa excepted), 187; Bright's disease, 156; suicide, 39; all other causes, 574.

International Congress on Tuberculosis in Washing-International Congress on Tuberculosis in Washing-ton.—Germany will be represented by thirty-five members; the leaders of the delegation will be Dr. Robert Koch, Dr. Martin Kirchner, and Dr. Lübe. The Norwegian Government has appointed as its delegate Dr. F. H. Harvitz, professor at the University at Christiania. The British Commission on Tuberculosis will be represented among others, by Dr. R. W. Philip, of Edinburgh, and Dr. G. Sims Woodhead, professor of pathology at the University of Cambridge, who is a member of the executive committee for Great Britain. Dr. Arthur Newsholme, chief medical officer of the local government board of England, will deliver a lecture on the Causes Which Have Led to will deliver a lecture on the Causes Which Have Led to the Decline in the Death Rate from Tuberculosis, and the Light Thrown by this History on Preventive Action for the Future. Professor Guido Vaccelli, of Rome, is the secretary of the Italian delegation, which consists of mem-bers of the universities of Turin, Naples, Florence, Bologna. and other cities.

New Hospitals.—The Italian born citizens of Philadelphia have decided to raise funds to erect an Italian hospital in Philadelphia.—It has been decided to erect a tuberculosis pavilion as an adjunct to the County Hospital at Denver, the estimate of which is about \$75,000.—The Hospital of St. Annhony de Padua, at Chicago, will be enlarged. The principal addition will be a five story structure, on the top floor of which will be an operating room. The cost of the extension is estimated at \$200,000.—Memphis, Tenn., is to have a hospital for consumptives. Dr. J. L. Andrews, president of the beard of health, intends to open such a hospital in a small way. As soon as the funds are available a large hospital will be erected.—The trustees of the Middlesex Hospital at Middletown, Conn., have voted to add a new building to the hospital, to be used as a nurses' home and a training school for nurses.—A project for the erection of a Swedish hospital has been started at Seattle, Wash.—The German Hospital at San Francisco, Cal., which has been lately dedicated, consists of two six story buildings which have been completed for the New City and County Hospital, San Francisco, Cal., at a cost of \$250.000. It is to be a three story, fireproof structure with a main building and two wings.

The Health of Philadelphia.—During the week ending August 8, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Typhoid fever, 42 cases, 5 deaths; scarlet fever, 16 cases, 3 deaths; chickenpox, 7 cases, 0 deaths; diphtheria, 26 cases, 5 deaths; chickenpox, 9 cases, 10 deaths; whooping cough, 29 cases, 9 deaths; pulmonary tuberculosis, 98 cases, 56 deaths; pulmonary tuberculosis, 98 cases, 50 deaths; pulmonary cases, 10 deaths; erysipelas, I case, I death; puerperal fever, 2 cases, 3 deaths; cancer, 17 cases, 22 deaths; mumps, I case, 0 deaths. The following deaths were reported from other transmissible diseases: Tuberculosis, other than tuberculosis of the lungs, 14; dysentery, 2; cholera morbus, 1; diarrhoxa and enteritis, under two years of age, 92. The total deaths numbered 482, in an estimated population of 1,532,738, corresponding to an annual death rate of 16,31 per 1,000 population. The total infant mortality was 160; under one year of age, 147; between one and two years of age, 22. There were 31 still births, 16 males and 15 females. The thermometer registered above 80° F. on five days, and on the other two days of the week the maximum temperature was 79° F. The total precipitation was 1.53 inches. There were 3 deaths from heat and sunstroke, 1 adult and 2 minors.

During the month of July 1998, 1,147 cases of contagious diseases were reported to the Department of Health, a decrease of 849 from the number reported in June. With the exception of tuberculosis and typhoid fever, all infectious diseases reported were fewer than for the preceding month.

Examination of One Hundred Eye Cases in the Dedham Public Schools, By RALPH WALDO PLACE.

The Immediate Treatment Demanded in Certain of the More Serious Ocular Conditions that are Frequently First Seen by the General Practitioner.—Cheney speaks of acute glaucoma. iritis, ophthalmia neonatorum, and perforating wounds of the eyeball. Of these he says: To lessen the chances of infection, or at least further infection, the lids and their immediate neighborhood should be thoroughly cleaned and the conjunctival sac irrigated with a boric acid or some other mild solution. It is impossible to make the conjunctival sac absolutely sterile, but if the patient is placed on the back, the lids separated, and the eye washed out with three or four dropperfuls of a boric acid solution, it will at least be clean. A one per cent. solution of atropine should be instilled three or four times at five minute intervals for the reason that iritis will develop in at least eighty per cent. of these perforating injuries. If atropine is not used, and numerous iritic adhesions take place, as they frequently will within the first twenty-four hours, they may very seriously interfere with the future successful treatment of the eye. If the anterior chamber is evacuated, the pupil will not dilate until it is reestablished. It is, nevertheless, advisable touse atropine so that its effects may be obtained as early as possible after the chamber begins to refill. Some simple nonirritating ointment, a piece the size of a pea, should be placed on the inner surface of the lower lid and the eye then bandaged. A good dose of Epsom salts, calomel, or some other active cathartic should be given, and a leech to the temple is good routine practice and at times is of the greatest value. When the eye is bandaged, if the pupil is well dilated, it is usually unnecessary to change it oftener than twice a day, the eye being thoroughly washed out, atropine instilled, and the ointment applied at each dressing. In injuries from dynamite, powder explosions, firecrackers, etc. where the conjunctiva and the lids are usually more or less burned and lacerated, exceptions are to be made in this treatment, especially as regards bandaging. Mucopurulent conjunctivitis is very liable to develop in these cases, and many eyes are lost by a secondary infection of the cornea. Closing up the eye by bandaging under such circumstances would certainly add to the danger of infection. The best results are to be obtained by washing out the conjunctival sac every fifteen or twenty minutes with a boric acid solution, applying boric acid ointment to the surface of the lids, and in using cold compresses for the first two or three days; not

omitting, of course, the instillation of atropine as often as the condition of the pupil may demand. A delay in transferring these patients to the care of an oculist is, of course, often unavoidable, but a special effort should be made in cases complicated by a prolapse of the iris requiring abscission, and also where the perforating object is a bit of steel lodged in the interior of the eye and whose removal necessitates the use of a magnet.

Therapeutic Immunization in Mixed Infection,

By A. P. Ohlmacher.

- 1. Acute Diverticulitis of the Sigmoid. Brewer thinks that if the diverticulum is small or attached to the bowel by a narrow pedicle, removal, with closure of the intestinal wound by a pursestring or several Lembert sutures, would be indicated, providing the surrounding intestinal wall was not too much infiltrated. In the event of the diverticulum being large, attached by a broad base, or covered by a plexus of enlarged vessels, the safest method, in his opinion, would be extraperitoneal drainage. If the situation of the lesion is such that extraperitoneal treatment cannot be carried out, packing with gauze should be adopted, from the abdominal wound to the lesion, leaving this packing in place from forty-eight to seventy-two hours, or until firm adhesions have formed about the gauze column; then removal of the gauze and free opening of the abscess, allowing it to drain through the channel thus formed. If rupture has already occurred the intestinal wound should be united by suture, if this is possible; if not, adequate drainage should be provided.
- 4. A New Technique for Nephropexy.-Ferguson describes the technique for nephropexy. Incise the skin, subcutaneous fat, and the muscles of the lumbar region down to the lumbar fascia, beginning the incision one inch below the tip of the twelfth rib and extending it the full length of the rib and parallel with it. Cut the presenting lumbar fascia obliquely below the twelfth intercostal nerves, which brings into sight the perirenal fatty capsule. Expose the kidney by vertically severing this fat. Deliver the kidney into the wound by the traction afforded by several artery forceps clamped on to the fatty capsule. This procedure is facilitated by ven-tral pressure. Place as much of the fatty capsule below the organ as is easily done where it may act as a support and a normal protection. Reform the

normal bed of the kidney if it has been obliterated by fibrous adhesions. This is best accomplished by means of a gauze pledget, grasped by a long curved forceps, and forcibly separate the encroachments of the liver and diaphragm on the normal renal fossa. Posterior and lateral adhesions are cut if necessary. To prepare the kidney for fixation, split the fibrous capsule over its convexity to within an inch or so of its lower pole and then peel it off the parenchyma of the organ, except at the lower end. Insert four catgut sutures, two to the anterior half and two to the posterior half of the capsule. With a long, round, curved needle the anterior sutures are passed subcutaneously from within outward and above the twelfth rib, while the posterior sutures are made to penetrate all the structures posteriorly at the upper angle of the wound except the skin. Often two retention sutures are enough. Gently push the kidney into the bed prepared for it and pull on the sutures. The kidney must rest in situ without any tendency to displacement after these sutures are tied. Otherwise adhesions in the renal fossa have been overlooked or the fatty capsule has not been properly dealt with. When there is plenty of room the anterior suture or sutures may be fastened to the diaphragm. In order to deepen the renal fossa and at the same time to support and fasten the lower end of the kidney, raise a broad, thin flap from the anterior surface of the quadratus lumborum muscle and suture it to the lower end of the kidney. Close the wound in the usual manner and leave room for a small cigarette drain at the upper angle of the wound.

- 6. The Diagnosis at Operation between Chronic Ulcer and Cancer of the Stomach .-Lund remarks that in certain cases of indurated ulcer of the stomach the diagnosis between benign and malignant disease may be impossible, even with the abdomen opened. These are the early cases, in which the diagnosis of early cancer is important, as enabling thorough removal. These cases, broadly speaking, fall into two classes: 1. Indurated ulcers (usually of the lesser curvature), which are movable and free and may be benign or malignant. Here, even if the tumor is benign, gastroenterostomy is often unavailing, and partial gastrectomy should be performed. Excision here is easy and safe. 2. Indurated ulcers of the pylorus often extending from the duodenum and adherent to the pancreas or left lobe of the liver. These are usually benign; excision is difficult, and gastroenterostomy is safe and should usually be performed rather than excision. In class I excision should be done regardless of laboratory findings. In class 2 the laboratory findings are important and usually reliable. The responsibility of leaving a tumor which may be malignant is so great, however, that all diagnostic aids should be invoked, and in case of doubt excision, though at some risk, may be performed. The surgeon must decide in each case whether the risk lies in performing excision or leaving a tumor which may be malignant.
- 8. Medical Education in the United States .-Bevan observes that the minimum American standard should eventually include the following require-

ments: A. The completion of a course in a high school such as outlined by the committee of ten of the National Educational Association, or, in other words, a high school having a four year course and which requires for admission the work of eight years in the elementary grades. This standard has been adopted by the Carnegie Foundation for admission to colleges of liberal arts. B. A thorough training in physics, chemistry, biology, and one modern language, preferably German, which would mean the equivalent of at least one year's work in our leading colleges of liberal arts. Many of the schools will require two years of this work, which may probably be the better plan. C. A four year course in medicine, which should include: (a) Two years of study, consisting largely of laboratory work, in anatomy (including histology and embryology), physiology, chemistry (including physiological chemistry), pharmacology, bacteriology and pathology; and (b) two years of chinical work largely in dispensaries and hospitals, including thorough courses in the practice of medicine (including physical diagnosis, pædiatrics and nervous and mental diseases), surgery (including surgical anatomy and operative surgery on the cadaver), obstetrics, gynæcology, materia medica, therapeutics, laryngology, rhinology, ophthalmology, otology, dermatology, hygiene, and medical jurisprudence. There should also be a course in clinical microscopy, including hæmatology. D. A year as an interne in a hospital. This last practical year is one of the most important in the course and should be made compulsory. Such a scheme of medical education is practical, concludes the author, and efficient, and it is possible for all medical schools which have any good reason for existence to come up within a reasonable time to this standard as their minimum requirement. It certainly would add strength to the movement to secure a high and uniform standard if our best institutions would adopt some such standard as has been outlined, which is practically the standard of Germany. One of the important functions of our great universities is to educate thoroughly competent medical men, and each one should turn out a large number of such men, not a limited number. Each should hold the same place in its community that is held by the great German universities and should provide largely the medical men needed in the section of the country in which it is located. Our better universities should not be put on a basis that will seriously limit the number of competent medical men, thus leaving the duty of supplying the great bulk of physicians to the poorer, illy qualified schools.

Amputation in Diabetic Gangrene,
By Eugene H. Eising.

Anæsthesia by Means of Chloroform and Ether, By EDWARD PENDITION

4. Chloroform-Ether-Ethyl Chloride Anæsthesia.- Meyer has used this chemical combination for ten years, seventeen per cent. volume of ethyl chloride mixed with eighty-three per cent. volume of molecular solution of chloroform and ether. This combination has a specific gravity of 1045, which is very close to that of the blood (1056 to 1059). According to volume, it contains seventeen per cent. of ethyl chloride, 35.89 per cent. of chloroform, and 47.11 per cent. of ether, representing a proportion of about 1:2:3. He also gives a hypodermic injection of morphine about one hour prior to the administration of the general anæsthetic. Anæsthesia is much more speedily induced in this way, and, besides, less of the narcotic is required in the course of the operation. With this anæsthetic, administered by means of the drop method and an Esmarch inhaler, the gauze of which is covered by some impermeable material with an opening in the centre, it will be observed that: I. Surgical anæsthesia is established in the majority of cases in about eight minutes. If morphine is previously administered, even this time is very frequently reduced by a few minutes. 2. The stage of excitation, if it sets in at all, is of very short duration. 3. Complete anæsthesia, having been gradually induced, the pulse is full and slow, of the chloroform anæsthesia type, and respiration regular, not stertorous. 4. In no instance has there been an increase in salivation or bronchial mucus during narcosis. 5. The face presents a healthy color. There is no pallor nor cyanosis. 6. If too little of the anæsthetic is given, the patient will begin to gag or vomit, as with chloroform; if too much is administered, respiration will become shallow, and, eventually, if still more is poured on the mask stop altogether, but the pulse will not be interfered with. In other words, the respiratory and not the circulatory centre is first affected by an overdose. There is, therefore, not the danger of the dreaded The tendency syncope, as with chloroform. throughout the narcosis is toward recovery from the effect of the anæsthetic, not toward a profounder anæsthesia; hence the advisability of administering it constantly, at a suitable rate and drop by drop. Of course, a careless narcotizer can kill a patient with this as well as any other anæsthetic. 7. After the anæsthetic has been stopped, the patient soon comes to, sometimes even while still on the operating table. If he sleeps longer, it is usually on account of the previously administered morphine. 8. Vomiting occurs in a small percentage of cases after return to consciousness. It is, however, not of a prolonged or distressing type. 9. Untoward after effects, such as bronchitis, pneumonia, nephritis, are not seen as a result of anæsthesia with this mixture. A preexisting catarrh of the bronchi or inflammation of the kidneys may, of course, become somewhat ageravated for a few days, but never to

the extent as happens after the inhalation of other gaseous substances. These complications certainly are never produced by this anæsthetic. 10. Patients afflicted with serious valvular cardiac lesions, chronic pulmonary affections, atheromatosis, diabetes, profound anæmia, or other complications of serious character, have stood this preparation most satisfactorily; contrary to what one would be justified in expecting in such cases, a better circulatory and respiratory condition was induced during anæsthesia. II. The total quantity used is generally small, his narcotizers very often carry a patient through an anæsthesia lasting from one to two

hours, with two to three ounces. 8. Amputation in Diabetic Gangrene.—Eising remarks that the hyperglychæmia is not an important factor in the induction of the gangrene, but looms into importance after gangrene has been established in so far that it invites septic infection and encourages the occurrence of phlegmon. Of the three acid bodies occurring in diabetes, acetone has a very low degree of toxicity, and probably does not contribute to the production of gangrene. Diacetic acid is always to be looked upon as a pathological ingredient of itself not very harmful and indicates that betaoxybutyric acid is being oxidized. Betaoxybutyric acid, when present in the urine, is to be viewed as the special chemical agent fostering gangrene, which, however, is ineffectual in bringing about that result if acting alone in the absence of arteriocapillary sclerosis. The quantitative ammonia excretion is the expression of measure of the amount of unburned betaoxybutyric acid. It is not an accurate standard of measurement, always registering too lit-The excretion of one gramme in twenty-four hours is to be looked upon as contraindicating operation except in great emergency. Nephritis is to be looked upon as a complicating circumstance, having little direct bearing upon the occurrence or course of the gangrene. It is to be considered, however, as an element of added danger in regard to operation and anæsthesia. Arteriosclerosis is the most important single factor determining gangrene in diabetes. Arterial disease is not caused by the diabetes; many protracted cases of diabetes are unaccompanied by arterial degeneration. The course of arteriosclerosis in the presence of diabetes is somewhat different from that unattended by diabetes. difference is probably due to the presence of betaoxybutyric acid in the blood in the latter instance. There is a difference between senile gangrene and diabetic gangrene. Senile gangrene is due to an end arterial ischæmia; the gangrene of diabetes is due to the same cause plus a devitalizing factor acting probably chemically. A knowledge of the tension is of value as a prognostic sign. Excessively high arterial tension is to be interpreted as an indication of advanced arterial change and probably interstitial nephritis. A low arterial tension indicates weakness from asthenia and secondary causes.

Malarial Cirrhosis of the Liver, By A. J. B. Duprey.
An Unusual Fracture of the Clavicle, By J. W. Rob.

4. The Blood in Ankylostomiasis.—Brehant states that it is now generally acknowledged that the anæmia in ankylostomiasis is due to a toxine, and it appears probable that the eosinophilia is, in a way, a measure of the amount of toxines circulating in the blood, the function of the eosinophiles being probably the formation of an antitoxine. The writer has made a series of blood examinations on adult natives of Egypt suffering from the disease. An analysis of these counts shows that the average percentage of the eosinophiles was small compared to the European percentages, and also that there were none of those high eosinophilic counts which have so frequently been described. The average was only ten per cent. and the highest individual count was thirty-six per cent. A possible explanation of this may be found in the fact that most, if not all, of the poorer Egyptians suffer from old standing bilharziosis which is constantly associated with an eosinophilia. It is probable that they are in a state of tolerance to toxines of a certain nature; and consequently in case of an increase in the amount of toxines circulating in the blood the reactioni. e., the eosinophilic change—would not be so great as in those who had never suffered from a previous toxæmia of a similar nature.

5. Cancer of the Jejunum.-Keyser reports a case of cancer of the jejunum occurring in a woman, aged thirty-eight years. Cancer of the intestinal tract is usually found at those points where there is a change in the lining epithelium of the canal, such as the junction of the esophagus and stomach, the anus, etc., or where the canal is subjected to some form of irritation, such as the sigmoid colon and rectum, the hepatic and splenic flexures of the colon, or the cæcum. The small intestine being a tube which is free from sudden bends and containing only liquid matter, is seldom attacked by carcinonia. Nevertheless it is occasionally the seat of cancer. Of the three portions of the small intestine-duodenum, jejunum, and ileumthe first named is much oftener affected than the other two; in fact cancer of the duodenum alone occurs about as frequently as cancer of the jejunum and ileum together. Cancers of the jejunum and ileum are characterized by their relative benignity, the small size of the tumors, the spheroidal celled nature of the growths, which resemble primary cancer of the vermiform appendix, and by not causing the death of the patients. The symptoms of cancer of the small intestine are practically the

same as those of the upper part of the colon viz., pain, often colicky in nature, a tendency to constipation with occasional diarrhœa, anæmia, and later in the disease, cachexia Occasionally repeated violent hæmorrhages from the anus are seen. A tumor can be felt when the disease is advanced, but is most difficult to find in the early stages owing to the mobility of the small intestine. When palpable it is, in the majority of cases, to be felt in the iliac fossa, most commonly the left, and not in the upper part of the abdomen. Vomiting is not uncommon, but symptoms of obstruction are rarely seen, unless the disease is close to the ileocæcal valve. The annular form of growth, so common in the large intestine, is rarely found. Sudden perforation of the gut with resulting peritonitis not uncommonly occurs, when death almost invariably follows. The average age at which the disease is discovered is 43.9 years. Cancer of the small intestine occurs in the two sexes with about equal frequency. The chief point of interest in the pathology is that the growth frequently shows spheroidal as well as columnar shaped cells. If the case is seen early enough or a growth is discovered during the performance of an exploratory laparotomy enterectomy and end to end anastomosis should be performed if this is possible. If symptoms of intestinal obstruction are present and the neoplasm is irremovable a lateral anastomosis should be done.

6. Treatment of Erysipelas.—Gray states that in considering the methods of treating cutaneous erysipelas it is necessary to mention both the local and constitutional means of combating the infection. With regard to local measures very little need be said, because the recovery of the patient depends less upon the treatment of the infected area than upon the means adopted to increase the general resistance of the tissues against the disease. The local treatment may be dismissed by saying that the infected part should be kept dry by dusting with powder; a mixture of calomel, starch, and zinc oxide in equal parts is usually cooling and welcome to the patient, as it relieves the burning pain so commonly complained of. The constitutional treatment may be medicinal only or combined with vaccination or the use of sera. The writer has obtained excellent results from Metchnikoff's serum, especially when combined with the internal administration of quinine, stimulants, etc. The results of the use of antistreptococcal serum were very variable. In all the cases a dose of from forty to fifty minims of Metchnikoff's serum was given.

7. Malarial Cirrhosis of the Liver.—Duprey holds that the cases of cirrhosis of the liver and ascites in children, met with so often in the tropics, are the outcome of a chronic malarial poisoning. The disease is a slow fibrosis, starting in the liver and spleen, and finally ending in interstitial nephritis. It is the result of repeated attacks of malaria, especially when neglected, upon young, unresisting, and possibly badly fed subjects.

Review of Hysteria by the Societé de Neurologie of Parts The So Called Hysterical Stiemata The "Pithiatic" and Trophic Troubles of Hysterical Percons. 2. Feetal Bronchopneumonia and Infantile Bronchiectasies.

By R. Romme.

1. Hysteria.—Meige reports the discussion by numerous speakers on this subject. It seemed to be the sense of the meeting that the so called stigmata not only lack the pathognomonic value lately attributed to them, but have a diagnostic signification, contestable and contested, which is of a secondary order. With regard to the question whether suggestion exerts an action on reflex phenomena, the accord seemed to be unanimous that suggestion is absolutely inefficacious over the tendinous and pupillary reflexes, and that former observations to the contrary were inexact. The diminution, abolition, or exaggeration of tendinous reflexes are not hereafter to be considered to appertain to the symptomatology of the paralyses and contractures called hysterical, and troubles with the pupillary reflexes are not met with in hysteria. Under hysteria is grouped clinical troubles, which may be recognized by the fact that they can be exactly reproduced by suggestion, and can be made to disappear under the influence of suggestion alone. The discussion is very interesting, but difficult to abstract.

 Anex. By Montelli and Cornillor.
- I. The Acidoalcohol Resistance in Its Relations with the Identity of Koch's Bacillus. - Auclair arrives at the following three conclusions: I. The investigation of the acidoalcohol resistance should be conducted in conformity to precise rules, otherwise it is impossible to determine this reaction and the findings are without value. 2. A bacillus resistant to acid which is not at the same time resistant to alcohol is not a Koch's bacillus, because every true Koch's bacillus is resistant to both. 3. But every bacillus resistant to acid and alcohol is not necessarily a Koch's bacillus; thus when in a secretion, particularly saliva, there are present bacilli resistant to acid and alcohol, short, stocky, abundant, and when the cells are placed parallel to one another, like those of a palisade, the suspected matter should be inoculated in an animal and a positive result obtained before a diagnosis of tuberculosis is made.
- 5. Diminution of the Vesicular Murmur at the Right Apex.—Montelli and Cornillot were struck with the frequency with which they met with diminution of the vesicular murmur at the right apex while making an examination of the school children of Bordeaux, in about 33½ per cent. of all cases, and further study has led them to the conclusion that this diminution of the vesicular murmur at the right apex is a normal physiological phenomenon.

the Bundle of His,

By J. KARCHER and G. SCHAFFNER. Concerning Soaplike Combinations as Complement, Angina and Miliary Tuberculosis, By Lublinsky.
The Intranasal Opening of the Maxillary Sinus,
By Sturmann.

By B. PRZEWALSKI Concerning the Great Omentum, The Bacteria and Leucocyte Double Staining in Studies Concerning Phagocytosis (Bacteriotropismus and Opsonization, By A. PAPPENHEIM.

10. Appendicitis during Pregnancy, Labor, and Childbed,

By ERNST RUNGE.

1. Diphtheria and the Serum Treatment .-Baginsky presents statistics drawn from the Kaiser und Kaiserin Friedrich Kinderkrankenhaus in Berlin and compares them with the statistics of the city of Berlin as a whole during the years 1905, 1906. and 1907. His conclusions will appear later.

2. Congenital Elephantiasis.-Nöggèrath describes the case of a slightly underweight, slightly rhachitic, psychically normal child, whose nutrition was very little interfered with, that presented a micropolyadenia, a slight anæmia, a tumor of the spleen, and a cushionlike thickening of both legs and feet. He believes this to have been a case of true congenital elephantiasis, which corresponded essentially with the acquired elephantiasis of adults.

3. Convergence Reaction in Reflex Immobility of the Pupils.-Lachmund reports a considerable number of cases of reflex immobility of the pupils which have come under his observation, and discusses the reasons why in some of them the re-

action of convergence was affected.

4. Adams-Stokes Disease with Induration in the Bundle of His .- Karcher and Schaffner contribute another case to the records of this rare condition, met with in a man, fifty-eight years of age. They find in literature only twelve cases of this discase in which a change in the bundle of His has been demonstrated on autopsy, and they present a full account of each of these cases.

Soaplike Combinations as Complement.-Von Liebermann and von Fenyvessy state that the complements are bodies constructed similarly to the unions or mixtures of soap and albumin in which other combinations of similar action may be substi-

tuted for either the soap or the albumin.

7. Intranasal Opening of the Maxillary Sinus. -Sturmann favors opening the antrum by an incision through the skin of the nasal aperture laying bare the maxillary bone by means of a curved raspatory and chiseling through the facial wall of the

8. The Great Omentum.—Przewalski makes a preliminary communication concerning the functions of the greater omentum, or rather of all parts of the omentum which are not evidently ligaments or suspensory ligaments, and have demonstrable mechanical functions. He presents the results of some experiments on dogs which go to show that the

omentain is a regulator of the peristalsis of the small

12. Radical Operation for Umbilical Hernias and for Epigastric and Subumbilical Hernias in the Linea Alba by Oblique Splitting of the Fascia and Shelling Out of the Muscle,

By Menge. 13. Obituary of Carl von Voit,

The Alternating Heart. - Hering asserts that the alternating heart is due to a part of the muscular fibres of the heart not responding to the stimulation at the time of the lesser systole. As this partial loss of reaction is present at the time of the lesser systole, but not at the time of the greater, we have to do with a periodically recurring partial asystole.

3. Treatment of Paralyses by Plastic Operations on the Nerves .- Spitzy reports two cases of paralysis of the region supplied by the peroneus successfully treated by implantation of the peroneus into the tibial nerve. He likewise successfully treated a case of radial paralysis, due to fracture of the arm at birth, by partial implantation of the median nerve into the radial when the patient was twelve years old.

4. Expectation Neurosis.—Isserlin describes several cases of what Kraepelin designated in 1904 as expectation neurosis (Erwartungsneurose). In these cases the expectation of an occurrence induces gradually increasing inner tension, which shows itself sometimes in certain false impressions, sometimes in all kinds of impulses to movement. If the anticipated occurrence is unpleasant and anticipations may be extremely tormenting and even painful. Of the functions that are interfered with by this trouble, that of reading is the most frequently affected and may be made impossible by flickering, sensations of tension, photophobia, and pain. Other functions affected may be writing, walking, standing, sleeping, swallowing, urinary, and sexual.

7. Spondylitis Cervicalis Deformans.-Preiser reports a case met with in a man, fifty-four years of age, which seems to support the views of those who asert that traumatism plays a certain rôle in the æti-

ology of spondylitis deformans.

1. The Treatment of Cancer of the Breast,
By J. B. Bissell.
2. An Improved Technique for the Radical Cure of CanBy F. G. Du Bose.
By M. Iverson

4. Practical Points in Anæsthesia,

5. Gastroenterostomy; Report of Three Cases with Observations as to the Physiological Effects on One Patient,

The Treatment of Gun Shot Wounds,
By George Franklin Shiels.

I. The Treatment of Cancer of the Breast.—Bissell remarks that without a better knowledge than we have at present of the cause, origin, and increase of that malignant lesion of human tissue called cancer, the only hope lies in surgery, early, completely, and extensively applied by means of the knife. Unfortunately, there is a limit to the promises even of surgery, but within its limitations its scope is powerful, certain, and wonderfully hopeful in the end results which it produces. We may assert, therefore, that as a result of modern surgical knowledge and operative technique and skill, the surgeon can assure to his cancer patients, if seen early enough, the definite certainty of a comparatively long life.

5. Gastroenterostomy. — Jones says that it appears that whether or not the gastric functions are interfered with; whether or not the food after gastroenterostomy passes through the pylorus or the stoma; whether or not bile regurgitates into the stomach; whether or not fat and proteid digestion are embarrassed—all are, in the face of clinical results, questions rather of academic, than of practical interest; and, therefore, when the operation of gastroenterostomy is indicated clinically, there is

no metabolic bar to its performance.

6. The Treatment of Gun Shot Wounds .-Shiels observes that if the intestine is perforated and not repaired the patient will die. The instrument inflicting the operation is not a matter of much moment. Prompt and immediate operation is imperative. It might be well to sound a warning for the guidance of the general practitioner, who, in the course of his work, occasionally meets with bullet wounds, and who may be tempted to probe or unnecessarily manipulate the wound with the object of cleansing it. Excluding wounds of the abdominal region and those which give rise to dangerous hæmorrhage, or pressure of the brain, and finally those in which the position of the bullet is clearly made out and its removal is not fraught with danger, simple aseptic dressing and awaiting developments is unquestionably the best policy. Of course, where bones are broken the ordinary treatment of bone fractures is in order.

THE JOURNAL OF NERVOUS AND MENTAL DISEASE August, 1908.

I. A Brain Tumor Localized and Completely Removed, with Some Discussion of the Symptomatology of Lesions Variously Distributed in the Parietal Lobe, By Charles K. Mills and Charles H. Frazier.

 Herpes of the Membrana Tympani: Due to Zosteroid Affection of the Petrosal Ganglion,

- By Thomas J. Orbison.

 Tabes Associated with Trophic Changes Suggesting
 Acromegaly, By F. X. Dercum.
- r. A Brain Tumor Localized and Removed.— Mills and Frazier report a case of brain tumor in a woman, forty-five years old. The patient was successfully operated upon, and the tumor, a simple scrous cyst, removed. The patient made a prompt

recovery. From the standpoint of physiology, especially as regards the functions of the parietal lobe and the possibility, in considering lesions of this lobe, of subdividing it functionally into several parts. the case was of much interest. The authors state that they have had the opportunity of studying at least four classes of cases, giving different symptom complexes, according to the degree of implication of the various portions of the parietal lobe. Possibly in time more than this number of syndromes can be separated for diagnostic purposes. These symptom complexes are: (1) Pronounced hemianopsia and ataxia, combined with pressure symptoms varying in intensity, such as hypæsthesia, hypastereognosis, and slight paresis of the face and limbs; (2) astereognosis and ataxia, combined with symptoms showing various degrees of involvement of cutaneous, muscular, and arthroidal sensibility, but without hemianopsia and with no or only slight paresis; (3) hemianopsia and hemiataxia, with hypæsthesia and hypastereognosis and pronounced paresis, especially of the face and upper extremity; and (4) astereognosis and ataxia, with hypæsthesia and pronounced paralysis, especially in the lower and upper extremities. These symptom complexes, more or less pure at first, become complicated as the tumor or cyst increases, and with it the variety and extent of the symptomatology. In considering the question of the position and extent of an opening for the removal of a tumor or cyst, the authors remark, the osteoplastic flap should be planned somewhat differently in accordance with these symptom complexes. For the first, in which pronounced hemianopsia and hemiataxia are the dominating symptoms, the incision for an opening three and a half or four inches in length for its superior boundary should be made, about one inch from the mesal edge of the hemisphere and in such manner that about one half of it should be cephalad and the other caudad, of the line of the parietooccip.tal fis-The base line connected by the somewhat converging sides of the opening should be over the upper part of the temporal lobe. With the second symptom complex in view-that in which astereognosis and ataxia, without hemianopsia, are the chief guiding symptoms-the opening should be carried as close as possible to the middle line of the skull, and should be an inch more anterior. The incision for the upper line of the third opening, for a case giving the syndrome in which hemiataxia, sometimes with hemianopsia and also with hypesthesia, impairment of the muscular sense and hemiparesis or hemiparalysis, especially in the face, are present, should extend about one third in front and two thirds behind the central fissure, and about one inch or one and one half inches from the median line, the base, as in the first opening, being over the temporal lobe. The incision for the upper limit of the fourth opening should be as near as possible to the midline of the skull, while its sides should be in about the same relative positions to the central fissure, that is so as to uncover the cerebral surface about one third in front and two thirds behind this fissure. By having the lines of the opening in the manner here indicated, the surgeon will probably find the main portion of the growth near the centre of the field of operation.

- Obstetrical Drawers. By J. G. DRENNAN.
- The Choice between the Intrapelvic and Abdominal Methods of Delivery in the Lesser (nonabsolute) Degrees of Mechanical Obstruction.—Reynolds affirms that while the elective Cæsarean section at the beginning of labor has, under favorable conditions, no greater material mortality than elective intrapelvic operations, lesser fœtal mortality, and less morbidity, the maternal mortality rises with the protraction of the duration of labor, the maternal mortality by intrapelvic methods remaining unchanged until very late in labor. We should therefore aim to recognize in advance the cases which must be subjected to operation. Repeated estimations of the capacity of the pelvis and of the vital resources of the patient will enable one to conduct labor cases with greater precision. The cases which promise great difficulty are not for the general practitioner unless he has the active cooperation of the obstetric expert. Mechanical difficulties in multiparæ which have already resulted in unfortunate labors indicate primary Cæsarean section, the same course being indicated for elderly primiparæ with similar difficulties. Moderate mechanical difficulties in young primiparæ may be met by intrapelvic operation, with the proviso that a subsequent pregnancy may necessitate Cæsarean section.
- 6. The External Ante Partum Examination .-Reed emphasizes the importance of such an examination at not later than the eighth month. It should determine the existence of pregnancy, the period of gestation, the attitude presentation, and position of the fœtus, the situation of the placenta, the presence of multiple pregnancy, the condition of the uterine and abdominal muscles, the relative size of the fœtus and mother, estimation of the size and shape of the pelvis by pelvic measurements, etc. An anæsthetic should be used if essential to thoroughness. Palpation is the most important element in such an examination; inspection and auscultation should also be employed. The patient lies in the dorsal position with thighs flexed. The physician first palpates the lower portion of the abdomen, facing the patient's feet, then the upper portion, facing the patient's head. Careful diagnosis thus made will often enable one to outline the course and the result of labor, and is of especial value, in many cases, in obviating the necessity for vaginal examinations during the progress of parturition.

 18. The Surgical Treatment of Bunion, By C. H. Mayo.
 19. A New Motor for Bone Surgery, By W. S. Bryant. Technique of Early Operation for the Re-
- moval of Tuberculous Cervical Lymph Nodes .-Dowd emphasizes the fact that thoroughness is all important in the removal of these nodes. All infected nodes should be removed when practicable. It is better to save life and leave scars than to sacrifice the patient, but it must not be forgotten that a scarsaving operation may be compatible with thoroughness. The arrangement of the infected nodes in early cases is almost uniform, and the technique for their removal as definite as that of the average surgical procedure. The skin incision is made a finger's breadth below the border of the jaw and should be parallel to a neck crease. The branch of the facial nerve must be retracted upward, and the sternomastoid muscle retracted backward. In separating the group of nodes the spinal accessory must be avoided. The internal jugular vein must be avoided in removing the lower group of nodes, the incision being enlarged to suit the situation. Drainage must be thorough, the wound being closed by subcuticular outlines except at the drain opening. Especial stress is laid upon the necessity of avoiding injury to veins.
- 4. Desmoid Tumors of the Abdominal Wall. Stone favors the view of Pfeiffer that these tumors are fibromata or fibrosarcomata arising from the musculoaponeurotic structures of the abdominal wall, thus excluding tumors originating from the bony pelvis, or the round ligaments, or the skin; or the subcutaneous tissues. Such tumors may first be discovered during pregnancy or the puerperium, though they occasionally occur in males. They usually present the typical picture of fibroma, and are most frequently found in the right lower quadrant of the abdomen. A scar or organizing hæmatoma is usually the starting point. They are seldom pain-

ful, vary in size from that of a hen's egg to that of a fist. Growth is usually slow and calcification may take place, but spontaneous disappearance has never been observed. The lymph glands are not involved unless the tumor is of a malignant type. The treatment is early operation. The longer they remain the greater their evil influence upon surrounding structures, and the greater the tendency to malig-

nant degeneration.

g. The Inconsistencies of the Gauze Pack.-Royster doubts whether the introduction of gauze into surgical practice has been as beneficial as some have believed. It is of undoubted value as a dressing and sponge material, but not always as a means for draining wounds, for packing sinuses, or for walling off septic material. The use of rubber tubes combined with gauze, and of rubber tissue enveloping it, is a distinct improvement. If used to arrest hæmorrhage it must be packed tightly; if for the evacuation of secretions it must be packed loosely. like a lamp wick. If used to wall off secretions it adds the danger of exposing to infection areas of peritonæum which nature may already have protected, and as a foreign body it impairs the resisting power of that membrane. Its removal is also accompanied by no little danger to the intestine from traumatism, or the diffusion of the septic material which it has absorbed.

Proceedings of Societies.

MEDICAL SOCIETY OF NEW JERSEY

One Hundred and Forty-second Annual Meeting, Held in Cape May on June 18, 19, and 20, 1908.

The President, Dr. Edward J. Ill, of Newark, in the Chair.

(Concluded from page 333.)

Acute Anterior Poliomyelitis, with Special Reference to the Recent Epidemic.—In this paper Dr. David T. Bowden, of Paterson, considered the actiology, the symptoms, the different stages, the diagnosis, the prognosis, and the treatment. He emphasized the fact that no operation should be performed, except possibly tenotomy, until some years after the primary infection, or without a thorough electrical test having been made to ascertain if possibly destruction of the muscle had taken place.

Dr. H. J. Bogardus, of Jersey City, gave statistics of 872 cases of infantile paralysis treated at the clinic of the New York Orthopædic Hospital in the period from January 1, 1897, to December 31, 1907. He stated that it had been estimated that half the crippled children wearing braces were doing so as the result of this disease, which must be considered as one of the most tragic things in the practice of medicine. It had been hoped, he said, that by a study of an epidemic of the disease occurring in a crowded American city a good deal might be learned concerning it; but, unfortunately, little had been added to the sum total of the previously existing knowledge regarding infantile paralysis.

Dr. D. E. ENGLISH said that he had suspected anterior poliomyelitis to be an infectious disease for some time, although this had not yet been proved to be the case. The few instances of the disease that he had seen had borne out the hypothesis of Dr. Bowden that it had some connection with acute or

chronic digestive troubles. Dr. English's patients had been very much constipated. In one case there was fæcal impaction, and he extracted from the intestine quite a quantity of chestnut shells, peanut shells, and pieces of coal. He thought that it would be interesting to know whether this depraved appetite had any connection with the disease. In all the few cases in babies that he had seen the infants had been fed with beer, and he thought that the effect of the alcohol on the infantile or childish system might

have some bearing upon the case.
Dr. Thomas P. Prout, of Summit, said that the results of nerve grafting did not bear out the expectations that had been formed regarding it in the first place; and he thought that probably the best that can be reported about it was simply an improvement in the general nutrition of the limb, which, of course, was worth something. Associated with this improvement, there was often for a long period an added palsy, on account of the engrafting of dead nerve tissue into the living structure. In regard to the treatment, he thought it wrong to torture these children with electricity. In the early stages, he said, the cases partook very largely of the nature of neuritis; and to stimulate the surface of the body with electrical currents during the course of a neurotic process had a torturing effect. Electrical treatment, therefore, should not be employed until four weeks had elapsed. He thought that it would be found that these cases belonged to the great number of latent infectious processes that became active only through lowered vitality and resistance on the part of the child, due to various causes.

Dr. Martin J. Synnott, of Montclair, referred briefly to one case that seemed to him to have some bearing upon the ætiology of the disease. The symptoms in this case pointed strongly to typhoid infection. A blood examination disclosed an enormous number of malarial parasites of the æstivoautunnal variety. The paralysis developed on the third day of the fever, and the subsequent course clearly pointed to poliomyelitis. Dr. Synnott wondered whether the malarial parasites could have had any bearing upon the poliomyelitis. He thought that there might have been a double infection. His experience had been that these patients improved as rapidly under the stimulation of vibratory massage as they did under that of either galvanism or faradism, and with

less discomfort.

Dr. W. M. LESZYNSKY, of New York, said that anterior poliomyelitis seemed to him a bad name for the cases that occurred during the recent epidemic, because a large number of them did not correspond to the usual type of this disease. A number showed the characteristics of encephalitis or myelitis, and, to a slight extent, of neuritis. He agreed with Dr. Prout in regard to the treatment. He did not think it necessary to examine thoroughly by means of galvanism in order to determine the presence of the reaction of degeneration. He scarcely considered it wise to wait until deformity had developed before instituting the orthopædic plan of treatment. One should accept the fact that a child with paralysis of the foot was likely to have foot drop, and should immediately place the foot in an apparatus to prevent the stretching of the anterior group of muscles.

Dr. L. GAUNT EDWARDS, of Williamstown, said

that, when used at all, electricity should be applied in its mildest form. If the muscle failed to respond after half a minute, the current should be stopped, as the already weakened muscle had been tired out. He had been much struck with the remark of Dr. English regarding the inflence of a depraved appetite in these cases, as only a few months before he had himself had a patient who would eat peanut shells, chalk, and coal, and relish them. Needless to remark, he had a good deal of gastric trouble.

Dr. Bowden said that he had thought that he had indicated in his paper that electricity should not be used until tenderness had subsided. As to how much should be employed, he thought that an amount sufficient to produce contraction should be applied. The idea of the therapeutic effect of electricity was that it was merely a massage of the muscles. This was why the orthopædic treatment had been recognized as of more importance than the electrical or neurological; it placed the child in a position to use any voluntary power that it might have. In the chronic stage, as soon as the child was able to carry a supporting apparatus, it should be put on. No one could reasonably question the benefit of electricity.

The Importance of Studying the Condition of the Heart Muscle in Various Diseases .- In this paper Dr. HOBART A. HARE, of Philadelphia, said that it was not his intention to deal with valvular changes, but with changes in the muscle (1) after acute overstrain; (2) after chronic overstrain; and (3) months and years after the overstrain had passed away. In the first class the murmur disappeared shortly after the exertion ceased. the second it persisted until after a long period of rest. It was not enough to diagnosticate the heart condition; its cause must be found. The great strain produced the great hypertrophy. After the age of forty-five the conditions al-The arteries still remained wide open pathways, but the heart acted less forcibly and the blood pressure fell. The final period of life was hurried upon the man, and he became prematurely aged in the fibroid changes, resulting in rigidity, which increased arterial tension, particularly when exertion was made, and threw a great strain upon the heart, which was unable to meet it. The attempt to do so brought about the hypertrophy of old age. One was frequently consulted by patients prematurely or actually aged who thought that their lack of health depended upon lack of exercise, when it depended upon other causes that should be corrected. It was one's duty to prevent

these patients from taking excessive exercise.

Dr. Philip Marvel, of Atlantic City, said that a subdivision of changes arising in the circulation into those attacking the endocardium and those attacking the myocardium must be made. In those attacking the myocardium one was often dealing with the results of some infectious disease that had preceded the first evidences of heart trouble, though perhaps not with the final results. He had been forced to conclude that heart conditions sometimes had their origin from a toxæmia. He wished to make a distinction between toxæmic causes and toxic causes. By the first he meant the conditions arising from bacterial changes peculiar to the food, and by the sec-

ond those conditions arising from bacterial causes external to the body. Toxemic causes might be bacterial, but they were from the bacteria of the intestinal tract, and not from those extraneous to it. In the second class of cases, those arising outside the circulatory organs, there was a mixed condition Primarily, there was the involvement of the circulation in the sclerotic changes in the vessels, and there was also the nutritive change, which was taking place simultaneously with the sclerotic change and involving the muscular fibres of the myocardium itself. Hence in this class of cases there were operative more than the causes that affected the heart from within the circulation. In regard to the class of cases that arose primarily from disturbances of the nervous system, it seemed to Dr. Marvel that one had to deal with causes of which the profession had little definite knowledge. They might have had their origin years before the patients were seen.

Dr. Martin J. Synnott, of Montclair, referred briefly to the use of hot carbon dioxide saline baths, combined with muscular exercise and so called resistance movements, as administered at Nauheim. Myocardial derangements responded most readily to this form of hydrotherapy. The results were not so good when the treatment was carried out at home.

Dr. ALEXANDER MARCY, Jr., of Riverton, emphasized the need of absolute rest in many cases of myocardial disease, particularly the acute variety. It should be continued for a sufficient length of time to allow the myocardium to recover its tonicity.

Dr. Hare wished to add one point to what he had already said. In listening to the hearts of persons whose general system did not seem much tired, one might often learn that the body was tired, because the heart sounds denoted it. A large proportion of so called cardiac cases did not depend upon valvular lesions, even when a murmur was present, the condition being due to relaxation of the mitral or tricuspid orifice. The cardiac sounds in such cases should be studied, not in connection with murmurs, but as indicative of the general tone of the circulatory system.

The Psychic Element in Medical Practice was the title of a paper by Dr. Linn Emerson, of Orange, who remarked that the practice of medicine was as much an art as a science. The art had been particularly prominent in early times, and there had been an undue prominence of the material side during the past century. Recently there had been a revival of psychic methods. Only men temperamentally fitted should be encouraged to begin the study of medicine.

Dr. T. N. Gray, of East Orange, said that early medicine was almost entirely psychic, the priest having been the physician. Through all the advancement that had been made in medicine along physiological lines, and with the newer knowledge of pathology, the ego of the physician still remained a powerful factor in the treatment. This influence was exerted through statements calculated to win the patient's confidence, and success was in proportion to the truth of these statements. Though there existed minds that could be affected by quacks, yet for every charlatan there are hundreds of general practitioners earning their living and keeping the confidence of their patients.

Dr. Leszynsky said that many members of the medical profession had inadequate or erroneous conceptions regarding the prevailing views as to the present psychotherapeutic agitation, and that others had given the subject no attention at all. Psychotherapy should not be characterized as a method confined to special forms of psychic analysis, persuasion, and hypnotic suggestion to the subconscious mind; within its sphere should be included isolation, educational measures, healthful occupation and diversion, and encouragement. Psychotherapy alone could not, in the majority of instances, supplant a rational plan of medical treatment, but it could be used by the average physician in connection with his daily work. Its practice as an exclusive method demanded special skill and training, and was applicable to selected cases only. It was by no means a panacea, its usefulness being limited. The recent wave of public interest in psychotherapeutics, fostered by a superabundance of literature on the subject, had naturally resulted in an exaggeration of its importance. The medical profession should take concerted action in attempting to prevent the practice of this form of therapy from being left unrestricted to the churches.

Dr. CHARLES A. ROSENWASSER, of Newark, thought it time that a warning should be sounded against believing much that was written in regard to the psychic treatment of various disorders. One could influence a man in a normal waking condition by talking to him, and one might also make suggestions to a man in a somnolent state, but Dr. Rosenwasser firmly believed that for a physician to talk to a person asleep would be wasting valuable time. Neither did he believe that a physician, when himself asleep, could influence another person.

Dr. WILLIAM G. SCHAUFFLER, of Lakewood, thought that one should be careful to avoid extremes. Certain books, while interesting to a careful, thinking man, were dangerous for the general public. Dr. Schauffler had recently spent several days in Boston, and had made careful inquiries regarding the work of the Emmanuel Church Clinic and of the men interested in promoting it. He had been told by one well known Boston neurologist that in the beginning he had taken great pleasure in sending patients to this clinic, because he had felt that the work there was conscientiously done; but that during the past few months he and others had had to give up sending patients there, because the work had so overwhelmed the men in charge of it that they were picking out only the most likely cases. Dr. Schauffler was also told that at the clinic they would not try to cure any alcoholics that could not state that they had the power to abstain from liquor if they wished to do so. He thought that, if this was the case, it was no wonder that they got ninety per cent. of cures.

Dr. Prour thought that the most important thing in regard to this matter would be for physicians to try to understand these phenomena. He had found that the laity, as a rule, expected the physician to scoff and jeer when these things were mentioned. The considered that looking at them in a derisive way would carry no weight with patients, unless one could show that such methods did positive harm. Dr. H. C. NEER, of Park Ridge, said that it was

undoubtedly true that such methods did a great deal of good, for it was not likely that all the persons that professed to have been cured were lying. He thought that after a time the method would find its right place, as almost all new methods met with opposition at first. He admitted, however, that its practice should be properly regulated, the same as that of any other therapeutic method.

Dr. EMERSON said that specialists and enthusiasts were always prone to overestimate the results in

such cases.

A Résumé of Modern Methods of Treatment for Posterior Displacements of the Uterus was the title of a paper by Dr. J. WATSON MARTINDALE, of Camden. The object of the paper, he said, was to point out the advantages and disadvantages of each operation and the conditions under which the different operations were indicated. The objects of operation for posterior displacement of the uterus were repair of the pelvic floor and the bringing forward of the uterus into a position of anteversion, The Alexander operation was the operation of choice in cases in which the perinæum was intact or had been repaired, if there is no evidence of disease of the uterus or its appendages, and if the uterus was not excessively large. He had had a bad result in only one case of this operation. Vaginal fixation with anterior colporrhaphy was useful in cases in which there was a cystocele and when the patient was beyond the childbearing period. The results in cases seen by Dr. Martindale had been excellent. Ventral fixation was of value in cases of procidentia, when the woman was beyond the childbearing period. It was usually first necessary to do an anterior colporrhaphy. The results of this operation were bad in women in the childbearing period. Ventral suspension was used in place of ventral fixation. The only difference between the two was that in ventral suspension the silk suture engaged only the peritonæum. Dr. Martindale, during the last two years, had seen ten patients subjected to section after having had the uterus suspended. The band of peritonæum supporting the uterus had in most of these cases stretched so as to give no support to that organ. Another objection to ventral suspension was the fact that it was not an anatomical operation. The Gilliam operation was devised to overcome the difficulty arising from fixation and also from suspension during the childbearing period. Gilliam proposed to shorten the round ligaments through an abdominal incision. Dr. Martindale had seen three patients operated upon by this method. The results were excellent, and no untoward conditions arose afterward. Simpson's operation, according to a modification devised by Dr. Charles P. Noble, of Philadelphia, had all the advantages of the preceding ones, and Dr. Martindale had heard of no serious objection to it. It was a recently invented procedure, so that he had had no opportunity to observe its effects upon subsequent labors. In twenty patients observed by him that were operated upon by this method the results had been good.

In retroversion following labor or miscarriage tamponing and the pessary were indicated. In retroversion with no adhesions and a moderate sized uterus the Alexander operation would be the proper procedure. In the case of women past the meno-

pause, when anterior colporrhaphy was required, vaginal fixation would probably be effective if the uterus was of moderate size. In procidentia uteri after the climacteric amputation of the cervix with ventral fixation would probably effect a cure. In procidentia during the childbearing period amputation of the cervix with ventral suspension, taking a strand or two of the muscle along with the peritonæum, would be suitable. In retroversion with a moderate sized uterus, when it was necessary to open the abdomen for inflammatory disease, shortening of the round ligaments after the manner described by Gilliam or Simpson would be the operation of choice.

Dr. Edward Staehlin, of Newark, said that the point in the résumé that had impressed him most was the description of the case of complete procidentia in the woman beyond the menopause. In such a class of cases he would recommend vaginal hysterectomy rather than the procedure recommended by Dr. Martindale. Dr. Staehlin considered chlorosis as an important factor in the production of retroflexion. He believed the Gilliam operation gave the best satisfaction as a method of restoration, and he always employed it. He did not think so much of the Alexander operation as of any of the others mentioned, and wished to know whether in performing it Dr. Martindale cut off the round ligament after it was fastened.

Dr. Martindale said that he cut off the redundant portion.

Dr. STAEHLIN suggested that it be left, giving as his reason that if, after it had been removed, anything should happen to the ligature, more trouble would be caused than was present before the operation. He then referred to the difficulty in finding an adequate means of restoring the pelvic floor. From the fact that there were so many methods of restoring the perinæum he thought it might be inferred that there were few of them that were adequate. A superficial tear down the median line, he said, might easily be overcome, but when the tear was lateral and very extensive there was a tendency to procidentia. In order to have a successful result the perinæum should be restored in an anatomical way. He considered preliminary amputation of the cervix a good point, and thought that the sound had proved to be a pernicious instrument. If a perforation was present, he believed in awaiting developments, as he felt convinced that in many cases of rupture of the uterus followed by a small perforation the wounds had healed spontaneously.

The President said that he did not believe that he anatomy of the condition was thoroughly understood. In his experience, retroposition of the uterus and produced a large number of pelvic symptoms with a pathological interest. He considered the Al-xander operation ideal, so far as anatomical condition went, but thought the Gilliam the most practical. By means of his own modification of this procdure he and his assistants had operated in about we hundred of these cases, with less than one and a laff per cent. of failures; and he thought that no ther operation could show so small a percentage. In Gilliam had told him that he was about to give p the operation that went by his name, on account if the large number of suppurative cases that he

had had. Dr. Ill's modification overcame this tendency, and he thought that its only possible danger was that the ligament might not be pulled out far enough. If it was pulled out so far as to prevent the tube from coming near the opening of the peritonæum and forming an adhesion, there would be no subsequent pain. Dr. Ill had seen a great many labors following his operation. In regard to ventral fixation, he had seen more damage done by this procedure than could be made good in a hundred years.

Dr. Gray said that he had wondered at not having heard some mention of the Webster operation, which had appealed to him as being satisfactory, simple, and effective. He wished to make a plea for more sections in cases of posterior displacement. While he had remarked the day before that he did not believe abdominal section to be altogether without danger, he thought that, comparing the slight danger attached to it with the benefit of the surgeon's knowing the whole pathology and being able to make a satisfactory support for the uterus, one must conclude that sections should be more frequent than they now were.

Dr. RECTOR said that the author of the paper did not seem to consider the fact that there were other things causing displacement than simple gravity, such as chronic metritis and salpingitis with adhesions. In order to relieve these conditions something else than the procedure described by Dr. Martindale was necessary. It appeared to Dr. Rector that all the operations mentioned were successful when applied to the proper conditions. The operation must be suited to the case. One should not say that if such and such a positive indication was present, one must do the Alexander operation, if another the Gilliam, and if a third the vaginal. Dr. Rector also remarked that Dr. Martindale had not stated that one must take into consideration the underlying conditions that had brought about the changes giving rise to the retroverted uterus, and said that if he were to advise looking into these conditions and treating them before an operation, the results would be better.

Dr. Chavanne remarked that it was the duty of the surgeon to make sure that his diagnosis was correct before inducing a patient to submit to an operation. He thought that many physicians had not sufficient sympathy with patients suffering from hysteria. He was satisfied that displacement of the uterus was often caused by the prudery of American women. Any medical man that did not take into consideration the history of the patient, her susceptibility, her emotions, and her occupation before making a diagnosis was committing an error.

Dr. Harvey said that he had not heard the part of the paper in which Dr. Martindale had mentioned the beneficial effect of pregnancy upon retrodisplacements. He thought that the general practitioner would bear him out in the statement that pregnancy had often cured retrodisplacements that had existed for some time.

The PRESIDENT stated that the late Dr. Munde had published some statistics in relation to this point, showing that only three per cent. of such patients got well after pregnancy.

Dr. Marvel said that with every retrodisplaced uterus there was a prolapse, and the fundus was

lower than it should be. An operation that would elevate the fundus of the uterus should be done. He admitted having had one accident whose cause Dr. Ill had cleared up for him, that of getting necrosis in fastening the round ligament in the Alexander operation. The stump of the ligament was, however, fastened sufficiently to the fascia of the rectum to hold the uterus in position. All things being equal, he considered Dr. Ill's modification preferable to the original Gilliam operation. The fact that it elevated the uterus made it the one in which there was the least likelihood of hernia or necrosis.

Dr. Drake, of Tennessee, said that imaginary diseases were real, material entities with a pathological basis, and the trouble could often be removed by diverting the patient's attention from the conditions that gave rise to the material images in the brain. The reason of there being so many operations for procidentia and for appendicitis in modern times, and so few in old times, was that the attention was now so often called to these particular organs through the prominence given to them by the operations of the surgeon. When the attention was concentrated for any length of time upon any particular part of the body, a pathological condition was finally produced in that part. If the attention of the patients could be turned away from their internal organs, Dr. Drake thought there would be fewer pathological conditions.

Dr. John P. Reilly, of Elizabeth, said that the discussion ought not to be closed without a further consideration of the shortening of one or both uterosacral ligaments, and he would be glad to hear from Dr. Ill upon this subject, because unmarried patients had persistent dysmenorrheaa, and married patients dysmenorrhea with sterility. All the suspensions done to relieve ordinary displacements would not cure this class of cases. All the ligaments on the front might be shortened and the floor repaired, but the case would not be cured.

Dr. Reilly thought it strange that silk had continued to be used so long in these suspensions, as catgut would give rise to much less suppuration and afford all the fixation necessary. It had occurred to him that in the method spoken of by Dr. Ill the posterior parietal peritonæum was lifted from the fascia below more than was necessary, and that this might do harm. He wished to know whether the posterior parietal peritonæum was stripped from the round ligament as it was brought through. He had stripped the peritonæum back so that he had the clear round ligament. By so doing he thought that the pushing upward of the peritonæum could be avoided.

The President said that removal of the ovaries was the operation most commonly performed for a short uterosacral ligament. In the physical examination, he said, the finger was passed into Douglas's cul-de-sac until it struck the tense cord, which was slightly pressed upon and found to be sensitive. There should be in the pelvic cavity no organ sensitive to slight pressure, and when the uterosacral ligament was so sensitive it was diseased. When the patient was put under ether, a finger was introduced into the vagina behind the uterus. The uterosacral ligament was caught on the end of the finger and was gradually brought outside. By massage the

ligament was lengthened, so that it was no longer tense and sensitive. As an additional safeguard against its contracting, it was kept on the stretch for a few days by thoroughly dilating the uterus. He always suggested that for two months following the operation the patients should use douches while on the knees and elbows, so as to keep up a little stretching of the ligament. He had sometimes had to do the operation the second time; and once it had to be performed a third time. When the changes in the uterus were not extreme, such as those produced by a chronic displacement, the patient usually got well. Two symptoms that should lead to a guarded prognosis were a sensitive spine and coccygeal pain. The pain on either side of the back, with inability to walk, was overcome by the treatment.

Dr. RICHARD C. NORRIS, of Philadelphia, said that sufficient stress had not been laid upon the preliminary treatment of the supports of the uterus and of the uterus itself. Years ago Emmet had cured a great many cases of displacement by means of careful plastic surgery followed by the use of the pessary. The wider his own experience grew, the more he was inclined to think that these operations to correct displacement had but a temporary effect. In regard to the selection of the operation for this purpose, he was glad to have found that the consensus in the New Jersey Medical Society was that the round ligament was the essential factor to be used, and that the portion of it that was the thickest and the nearest to the uterus was the one best fitted to accomplish the work. He was also glad to hear that ventral suspension or fixation should be discarded. At the Preston Retreat, in Philadelphia, there had been during the last fifty years 3,500 confinement cases, and Dr. Norris had found that in those in which ventral fixation had been used, complications in childbirth frequently occurred. had led him to believe that this operation ought to be abandoned. Even the technique that prepared for a suspension, he said, might eventuate as a fixation. It was his opinion that an operation for holding the uterus in position by means of the round ligaments would be devised that would not fasten the uterus to the abdominal wall. He had had no difficulty in regard to sloughing or hernia in either the Gilliam or the Simpson operation. He had used the procedure suggested by Dr. Ill, which had appealed to him surgically and clinically as being the most satisfactory. He was surprised that the gentlemen had failed to appreciate the Alexander operation, as he believed that there existed a class of uterine displacements in unmarried women in which this operation found a wide field of usefulness. When performed with careful technique, there was no danger of sloughing or of infection.

Df. MARTINDALE said that if a vaginal hysterectomy was done in cases of procidentia, the condition would not be cured. It was absolutely necessary to do the plastic work before any of these operations were attempted, a point that he thought he had made plain in the paper. Dr. Ill had described a method of treatment for a tender and shortened uterosacral ligament. Dr. Martindale said that he would feel a little hesitation about employing this treatment unless it was carried out by a skilled operator, as some other structure might be mistaken for

this, and damage might be produced by the massage. He was not familiar with the Webster operation, and consequently could not speak about it. thought that the proper treatment for a case of chronic metritis or salpingitis with adhesions would be supravaginal hysterectomy, which was a safer procedure than double oophorectomy with oophorosalpingectomy. He had seen cases of inflammation of the broad ligaments and the ovaries in which, when the finger was pushed into the body of the uterus, the whole structure was found to be broken down. He had seen the good effect of pregnancy upon a backward displacement of the uterus exemplified. One of the disadvantages of ventral suspension consisted in the use of silk sutures. In the clinic to which he belonged the suture material universally employed was catgut. He believed that the danger from the premature absorption of catgut was less than that from the presence of a foreign body such as silk in the abdominal cavity. In many cases the silk ligatures became infected and caused suppuration. He thought that the reason women formerly did not appear to have procidentia was that they did not then consult physicians for this trouble, and that if they had, they would not have obtained relief. He had never done the operation for shortening of the uterosacral ligament, but had seen it done in three cases in the course of the operation for bringing the uterus forward. He wished to take exception to the attitude of both speakers in regard to ventral fixation, which he believed to be the operation par excellence in women beyond the climacteric, although he considered it criminal to do this operation on a woman during the childbearing period. The suspension that took in one or two strands of the muscle he thought more effective than the ordinary suspension, in which merely the peritonæum was used. In case of a large uterus, with lax vaginal and abdominal walls, better support was afforded by ventral fixation than by any of the other operations mentioned. The sixth operation described by him was not the Simpson operation, but a modification of it devised by Dr. Charles P. Noble, of Philadelphia; it is quite similar to the operation described by Dr. Ill. If the ligament was taken up and drawn through the abdominal cavity, the inlet to the pelvis would be divided into three distinct artificial compartments. This was not anatomical, and was likely to produce strangulation of the bowel.

Book Rotices.

Modern Medicine. Its Theory and Practice. In Original Contributions by American and Foreign Authors, Edited by WILLIAM OSLER, M. D., Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore, etc., Assisted by THOMAS MCCRAE, M. D., Associate Professor of Medicine and Clinical Therapeutics in the Johns Hopkins University, etc. Volume IV. Diseases of the Circulatory System—Diseases of the Blood—Eases of the Spleen, Thymus, and Lymph Glands. Illustrated. Philanelphia and New York: Lea & Febiger, 1908. Pp. ix-17 to 865.

This is one of the most valuable volumes of this

great work which have thus far appeared—for two reasons, because the subjects treated of are for the most part diseases with which the general practitioner has frequent occasion to contend, and because the choice of authors has been singularly felicitous. The opening chapter, entitled General Considerations in Cardiovascular Disease, is by Dr. Charles F. Hoover, of the Medical College of the Western Reserve University. It is a scholarly and exceedingly satisfactory discussion of certain points of great practical importance in connection with discases of the heart and bloodvessels.

Chapter ii, dealing with diseases of the pericardium, is by A. McPhedran, M.B., professor of medicine and clinical medicine in the University of Toronto. The subjects considered are pericarditis, adherent pericardium (well characterized by the author as, "properly speaking, only the adhesion of the two layers of the pericardium resulting from divers forms of pericarditis, and therefore neither a disease nor an affection," but as presenting such special clinical signs and being associated with such lesions within and without the pericardium as to merit separate description), tuberculous pericarditis, hydropericardium, hemopericardium, pneumopericardium, and neoplasms, syphilis, and complete and incomplete deficiency of the pericardium. The chapter is marked by the excellence which stamps all of Professor McPhedran's writing.

Chapter iii, on diseases of the myocardium, is the work of Dr. Robert H. Babcock, of Chicago. It is an instructive essay on the inflammatory, infective, and degenerative affections of the muscular substance of the heart and on new growths and parasites of that structure. It is interesting to note Dr. Babcock's remarks on the abuse of alcohol in the ætiology of myocardial degeneration. He says: "On the whole, the writer is inclined to the view that the degeneration of the myocardium found in drunkards is not attributable so much to the alcohol as to impurities contained in the vile stuff they drink, for it is a known fact that men who drink only the best and purest whiskey often consume a quart or more daily for a lifetime without displaying more evidence of heart disease than do their strictly temperate brethren.

He thinks that the so called resistance exercises are not so beneficial as breathing exercises and other lighter gymnastics, though "if the degree of resistance is properly applied to the patient's condition, the movements lighten the labor of the heart." In regard to the Nauheim baths, he remarks that it is not customary at Bad Nauheim to begin a course of treatment with carbonated waters, and he deprecates the misleading statements of certain manufacturers who magnify the ease with which imitation Nauheim baths may be administered in the patient's own home and the benefit alleged to follow their use. The reader should by all means ponder what Dr. Babcock has to say about medicines which act on the heart, especially aconite, beginning on page 122.

The fourth chapter, on acute endocarditis, is by Dr. Osler; the fifth and sixth, on hypertrophy of the heart and on insufficiency and dilatation, are by Alexander G. Gibson, M. A., B. M., M. R. C. P., of the Pathological Department of Oxford University; and the seventh, on diseases of the valves, is the

joint production of those two writers. In the chapter last mentioned, on page 222, there is a very satisfactory account of the Flint murmur, and all three of the chapters are excellent. We would particularly commend the paragraphs on digitalis, beginning on page 265. Chapter viii, on functional diseases of the heart, is the work of Dr. Hoover, and it is exceedingly instructive. In chapter ix, on congenital cardiac disease, by Dr. Maude E. Abbott, of McGill University, we find instructive accounts of many pathological conditions which are not usually treated of in textbooks. Dr. Abbott makes extensive use of the German word Rechtslage; it certainly has the advantage of brevity. In chapters x and xi Dr. Osler deals with diseases of the arteries; chapter xii, by Dr. George Blumer, of the Yale Medical School, is on thrombosis, embolism, and phlebitis; and Dr. Aldred Scott Warthin, of the Department of Medicine of the University of Michigan, finishes the first part of the volume with a chapter on diseases of the lymphatic vessels. All these writers deal acceptably with their themes.

Dr. Richard C. Cabot, of the Medical School of Harvard University, contributes the first and second chapters of Part II (chapters xiv and xv of the volume), on the general pathology of the blood forming organs and on pernicious and secondary anæmia, chlorosis, and leuchæmia. We are glad to see these positive statements in his section on chlorosis: "Chlorosis is one of the four or five diseases now known to us which can be cured with a drug; despite some hypercritical skeptics, there is no longer the slightest doubt of this fact. In any case of supposed chlorosis which does not yield readily to iron administered in the proper manner and in the proper dose we have reason for doubting the diagnosis." Dr. Cabot questions the propriety of Leube's term leucanæmia until the supposed condition can be more definitely diagnosticated; and we think he is right. Chapter xvi, on purpura and hæmophilia, is by Dr. Joseph H. Pratt, of the Medical School of Harvard University. It is a very satisfactory chapter.

Part III opens with chapter xvii, on diseases of the spleen, by Dr. Irving Phillips Lyon, of the Medical Department of the University of Buffalo. Dr. Lyon's account of kala-azar (tropical febrile splenomegaly) is particularly interesting. Chapters xviii and xix, on diseases of the thymus and on diseases of the lymphatic glands, by Dr. Warthin, conclude the volume. The author stoutly combats the dictum that there is no such thing as thymic asthma. His descriptions of that affection, of thymic stridor, and of the relation of thymic disease to sudden death are good examples of vigorous and convincing writing.

In general, the mechanical work on the volume has been well done, but we find far too many evidences of inadequate proofreading. We will cite only some of the worst of them. In the list of contributors Dr. Babcock is mentioned as connected with the "Mariam-Sims" Hospital; on page 19 we find the following foot note: "Mass der Ernüdung der gesund und Kranken Menchen" (which should be Mass der Ermüdung der gesunden und kranken Menschen); on page 264 there occurs the expression "hydrochloride acid"; and on page 681 we find "data is" (in the foot note). It is a pity that such a noble work should be so disfigured.

Studies from the Institute for Medical Research, Federated Malay States. Volume III, part 3. Breeding Grounds of Culicida, by C. W. Daniels, M. B. (Camb.), M. R. C. S. (Eng.), Director of the Institute for Medical Research, Federated Malay States. The Culicidæ of Malaya. By G. F. Leicester, M. B., C. M. (Edin.), Assistant in the Institute for Medical Research, Federated Malay States. Singapore, Shanghai, Hong Kong, and Yokahama: Kelly & Walsh, Limited, 1908. (Price, 1s. 6d.)

The third part of volume three of the Studies from the Institute for Medical Research, located at Kuala Lumpur, Federated Malay States, is a technical volume on the mosquitoes of the peninsula. The volume opens with a paper by Dr. C. W. Daniels, formerly director of the institute, but now of the London School of Tropical Medicine, on the breeding grounds of the various mosquitoes to be found in Malaya. This is followed by a description by Dr. Leicester of the various mosquitoes found in the peninsula. The volume was in press when the fourth volume of Theobald's Monograph of the Culicide of the World was published, so that some of the species described in this volume will be found to have different names in the book by Theobald. The book will be of great value to those working in medical entomology.

Miscellany.

A Study of One Hundred Refraction Cases in Indians Fresh from the Plains .- Dr. Jones makes a report of one hundred cases, covering 289 admissions at the Hampton (Va.) Normal and Agricultural Institute. The percentage having refractive errors necessitating the wearing of glasses to improve vision and to relieve symptoms of eyestrain was 34.6 per cent. The ages were from 14 to 22; males, 127, in this series 44 cases, or about 35 per cent.; females, 162, in this series 56 cases, or about 34 per cent. On admission a careful test of vision was made, and when it was below 20/20 in each eye, or when the usual symptoms of eyestrain developed subsequently, a thorough refractive test was made. In making this test careful and systematic use was made of the ophthalmometer, ophthalmoscope, retinoscope, phorometer and test lenses, employing a cycloplegic in every case. In these 100 cases-200 eyes-the refractive varieties found were as follows: Hyperopia, 38 eyes; simple hyperopic astigmatism, 26; compound hyperopic astigmatism, 60; myopia, 13 eyes; simple myopic astigmatism, 15; compound inyopic astigmatism, 32; mixed astigmatism, 16. The axis of hyperopic astigmatism was 90 degrees in 69 eyes, 180 degrees in 5, 45 or 135 degrees in 5, nearer vertical than horizontal in 13, and nearer norizontal than vertical in 6. The myopic axis was 180 degrees in 38 eyes, 90 degrees in 4, 45 or 135 legrees in 4, nearer vertical than horizontal in 4, and nearer horizontal than vertical in 15. There vere 3 cases of heterophoria amounting to as much is 2 degrees, no case being treated other than corecting the refractive error. No strabismus. A narked tolerance for cycloplegics existed in the Inlian. Scopolamine was not effective, being practicalworthless. Homatropine, 1/25 grain in each eye, pplied by means of gelatin discs, was usually reliale; this dose was repeated in thirty minutes in bout 10 per cent. of the cases. Atropine was necssary in 3 cases. A less than 2 per cent. solution f the latter was ineffective; also the strong soluon of atropine was found necessary when its efect was desired in treating eye injuries of Indians ccurring in the school work shops. Fifty-one, or 7.65 per cent. of the whole number, had trachoma 1 entrance, 16 cases in this series; the remaining 5 had normal vision. All trachoma patients were eated surgically, being promptly rolled by Knapp's rceps, and active after treatment. In the 16 cases

mentioned in the refractive series, the test was not made till the acute symptoms had subsided and the corneæ became clear. The care exercised by officers, physicians, and nurses with these patients has prevented the spread of the disease at the institution.—The Journal of the American Medical Association

Public Health and Marine Hospital Service:

Official list of changes of stations and duties of commissioned and other officers of the United States Public Health and Marine Hospital Service for the seven days ending August 12, 1908

COBB. J. O., Surgeon. Directed to proceed to Chicago, Ill., for special temporary duty, upon completion of which to rejoin his station at Milwankee, Wis

Dunn, James, Acting Assistant Surgeon. Granted leave of absence for thirty days from August 17, 1908.

Gahn, H. E., Pharmacist. Granted leave of absence for

eleven days from August 10, 1908. Goldberger, J., Passed Assistant Surgeon. Detailed to represent the service at the International Fishery Congress, to be held in Washington, D. C., September 22 to 26, 1908.

GUSTETTER, A. L., Acting Assistant Surgeon. Granted leave of absence for two days from August 10, 1908. HICKS, B. I., Acting Assistant Surgeon. Granted leave of absence for twenty-three days from August 14, 1908.

McGinnis, R. H., Acting Assistant Surgeon. Leave of absence granted July 17, 1908, for fifteen days from August 17, 1908, revoked.

MEAD, F. W., Surgeon. Granted leave of absence for one

month from August 26, 1908.

MILLER, W. W., Assistant Surgeon. Granted leave of ab sence for six days from July 27, 1908, under paragraph 191, Service Regulations.

SEAVEY, L. T., Acting Assistant Surgeon. Granted leave of absence and amended so as to grant him twenty-one days from August 3, 1908.

SWEET, E. A., Assistant Surgeon. Granted leave of absence for two months from August 18, 1908.

TARRELL, B. C., Acting Assistant Surgeon. Excused from duty without pay, August 31 to September 30, 1908, inclusive. Vogel, C.

EL, C. W., Passed Assistant Surgeon. Relieved from special temporary duty at San Juan, Puerto Rico, and directed to report at the Bureau, Washington, D. C. Wakefield, H. C., Acting Assistant Surgeon. Granted leave of absence for twelve days from August 8, 1908. Woodward, R. M., Surgeon. Granted leave of absence for Walley and State of Stat

thirteen days from August 24, 1908.

Promotion.

Pharmacist Newton C. Comfort, promoted to pharmacist of the second class.

Dr. Leroy M. Stowe, appointed an acting assistant surgeon for duty in the office of the American consul at Tampico, Mexico.

Boards Convened.

A board of medical officers was convened to meet at Baltimore, Md., August 12, 1908, for the purpose of making a physical examination of a surfman of the Life Saving Service. Detail for the board: Passed Assistant Surgeon J. T. Burkhalter, chairman; Assistant Surgeon H. J. Warner, recorder.

A board of medical officers was convened to meet at San Francisco, Cal., August 14, 1908, for the purpose of making a physical examination of an officer of the Revenue Cutter Service. Detail for the board: Surgeon H. W. Austin, chairman; Passed Assistant Surgeon W. W. King, recorder.

Army Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Army for the week ending August 15, 1908:

Anderson, E. H., First Lieutenant. Ordered to return to station, Fort Wingate, N. M., from duty in field.

BIRMINGMAM, H. P., Lieutenant Colonel. Detailed mem-

BIRMINGMAM, H. P., Lieutenant Colonel. Detailed member of examining board, appointed in paragraph 28, S. O. 98, April 25, 1908, War Department, vice Colonel Charles B. Byrne, Medical Corps. So much of paragraph 5, S. O. 152, June 29, 1908. War Department, as directs the officers therein named to report to Colonel Charles B. Byrne, Medical Corps, as president of the examining board, is amended so as to direct them to report to Colonel Valery Havard, Medical Corps, president of the board, vice Colonel Byrne.

BLANCHARD, ROBERT M., Captain. Leave of absence for ten days is extended twenty days.

CRANTEEE, GEORGE H., Captain. Left Ancon, Canal Zone, on leave of absence for fifty-four days.

on leave of absence for fifty-four days.

Heysinger, James D., Captain. Granted leave of absence

Huber, Edward G., First Licutenant. Left camp at Chick-amauga Park, Ga., for camp at Fort Riley, Kan. Koerper, C. E., Captain. Granted leave of absence from Cuba, to commence about September 11th and ending

October 7th, with permission to visit the United States.

LAMBIE, JOHN S., JR., First Lieutenant. Left camp at Chickamauga Park, Ga., for camp at Fort Riley, Kan. REYNOLDS, CHARLES R., Captain. Left camp at Chicka-mauga Park, Ga., for camp at Fort Riley, Kan. Scott, George H., Captain. Granted leave of absence for

one month after return of troops from maneuvre camp.

Suggs, Frank, First Lieutenant. Ordered from Fort
Niagara, N. Y., to Fort Washington, Md., for temporary duty during the absence of Captain Samuel J.

Morris, Medical Corps.

TROTTER-TYLER, GEORGE, First Lieutenant. Ordered from Fort Adams, R. I., to Fort Monroe, Va., for temporary duty

duty.

The following named majors have been ordered to report in person, on September 21, 1908, to Colonel Valery Havard, Medical Corps, president of the examining board at the Army Medical Museum, Washington, D. C., for examination to determine their fitness for promotion: H. S. T. Harris, Edward R. Morris, William P. Kendall, Henry I. Raymond.

Navy Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Navy for the week ending August 15, 1908:

BOYD, J. C., Medical Director. Detached from command of the Naval Medical School Hospital, Washington, D. C., and ordered to continue duties as president of the Naval and Medical Examining Boards at that

school.

Cohn, I. F., Assistant Surgeon. Ordered to the Naval Hospital, Mare Island, Cal.

Harmon, C. E. H., Medical Director. Ordered to command the Naval Medical School Hospital, Washing-

HAYWOOD, A. B., Assistant Surgeon. Detached from duty with the marine detachment at Camp Ellicott, Isthmian Canal Zone, Panama, and to the Naval Recruiting Sta-

tion, Pittsburgh, Pa.

Shephard, C. W., Assistant Surgeon. Detached from the
Naval Hospital, Mare Island, Cal., September 1st, and
ordered to the Naval Medical School, Washington,

D. C., October 1st, for instructions.

TURNER, H. W. B., Assistant Surgeon. Appointed assistant surgeon from July 29, 1908.

URIE, J. F., Surgeon, retired. Ordered home, when discharged from treatment at the Naval Hospital, Marc Island, Cal.

Births, Marriages, and Deaths.

Durgin—Adams.—In Boston, on Wednesday, August 12th, Dr. Samuel H. Durgin and Mrs. Emma Elizabeth

EISAMAN—PERCY.—In Atlantic City, New Jersey, on Saturday, August 1st, Dr. Ollie N. Eisaman, of Pittsburgh, and Miss Alice Percy.

SIMS—SICKEL—In Philadelphia, on Wednesday, August 5th, Dr. Nelson I. Sims, of Kalamazoo, Michigan, and Miss Irene F. Sickel.

STAFFORD—SKINNER.—In Herkimer, New York, on Wednesday, August 5th, Dr. Rosslyn J. Stafford and Miss Ora Skinner.

Burr.—In South Framingham, Massachusetts, on Thursday, August 13th. Dr. Charles H. Burr, formerly of New York, aged fity-three years.
GLENN.—In Norfolk, Virinia, on Tuesday, August 11th, Dr. Frank B. Glenn, aged thirty years.
HABRSHAW.—In Saratoga, on Sunday, August 16th, Dr.

M. Habirshav Lowber.—In Wilmington, Delaware, on Wednesday, August 12th, Dr. Alexander Lowber, aged sixty years.

SMITH.—In Gaincsville, Georgia, on Friday, August 7th, Dr. K. A. Smith, aged thirty-eight years. WHEAT.—In Philadelphia. on Wednesday, August 12th, Dr. Lewis E. Wheat, aged forty-five years.

THE TREATMENT OF TUBERCULOSIS BY THE ADMINISTRATION OF MERCURY

at the U. S. Naval Hospital, New Fort Lyon, Colorado.*

BY SURGEON BARTON LISLE WRIGHT, United States Navy

About six months has elapsed since we began to treat tuberculosis by deep muscular injections of miercury, during which time two reports have been published, the first in the April number of the United States Naval Medical Bulletin, the second in the July number of the same magazine.

In the latter issue we reported the results of forty cases then under treatment (May 25, 1908) showing seventy per cent. of improvements, or twentyeight cases improved, out of the forty so treated, many of which were quite marked.

Since that date the percentage of improvements among these forty cases has risen to eighty-five, or thirty-four cases improved.

We now have sixty-five patients taking the treatment, and from present indications the percentage of improvements will equal, if not surpass, that obtained from the forty already reported.

A few of these patients have moderately advanced lesions, but the most of them are well or far advanced cases, which emphasizes in a marked degree the value of mercury as a curative agent in this dis-

We now have one hundred and six patients in the hospital, sixty-five of whom are voluntarily taking the injections; of the forty-one not taking the injections but a few are improving, and in these the improvement is mostly confined to their general condition, the extent of their pulmonary lesions remaining unchanged, or if improved, but to a slight

Among the one hundred and six patients we have twelve officers, who are living in old dwelling houses, repaired to meet the emergency, with very small porch areas for out door life, while the enlisted patients are quartered in modern open air wards of the most approved type, or in large tents.

To offset the disadvantages under which the officers are living at present, owing to the uncompleted hospital facilities, we have their superior intelligence, which is that of the average educated man. This renders them more susceptible to advice; to this, and their evident anxiety to get well as quickly

as possible, so that they may resume their professional duties, I attribute their rapid progress.

Of the twelve officers under treatment, two have refused to take the mercurial treatment. Of these two patients one has progressively failed, the second has about held his own.

The other ten are taking mercury, and nine are rapidly improving, or ninety per cent., while one has failed slightly (Case V). This patient was admitted April 9, 1908, and since admission has ridden horseback rather vigorously, in addition to which, he spent some twenty days' leave in the East, during which time he indulged in swimming, canoeing, and horseback riding, and did not receive the mercurial treatment, all of which has tended to retard his improvement.

The following detailed report of the above twelve patients in the order of their admission, well demonstrates the efficiency of mercury in the treatment of tubercular disease.

CASE I.-J. T W., carpenter, U. S. N., admitted May

Family history. Paternal grandfather, killed in an accident; paternal grandmother, died of old age; maternal grandfather, died of old age; maternal grandmother, died of old age; father, died in forty-ninth year of abscess of brain; mother, living and in excellent health; one brother, killed in an accident; one brother living, in good health; three sisters living, in excellent health.

Personal history. Born December 20. 1871, at Balti-

Personal history. Born December 20. 1871, at Baltimore, Md.

During childhood had measles; when about four years of age had pneumonia. Between this time and November, 1902, was perfectly well. About November, 1902, while serving on the U. S. S. Monongahela, contracted a cold for which he received treatment. In December, 1902, while at sea, en route to the West Indies, diagnosis of pulmonary tuberculosis was made. Sputum positive for tubercle bacilli, and physical signs noted in left lung. On January 31, 1903, was detached and ordered to the U. S. Naval Hospital, New York, arriving 8th of February, 1903. Was detached and ordered to the U. S. Army General Hospital, Fort Bayard, N. M., where he reported March 4, 1903. He improved considerably, and was discharged from Fort Bayard, July 25, 1905, in very good condition, but his sputum would occasionally show the presence of tubercle bacilli. He reported to the Retiring Board in Washington, D. C., on the 14th of August, 1905; the board found him "temporarily incapacitated for active duty," and recommended "six months sick leave" At the expiration of this leave, he reported to the same board, by order of the Navy Department. The board found him "fit for duty." He was ordered to the Naval Station, Hawaii, for duty. He performed duty, and enjoyed fairly good health until the latter part of February, 1907 (with the exception of losing weight).

At this time he began to grow weak, to cough, and to

the latter part of February, 1907 (with the exception of losing weight).

At this time he began to grow weak, to cough, and to have slight expectoration. During the first week in March, 1907, had a severe attack of what was diagnosticated as influenza. The symptoms at this time were repeated chills, high fever, and severe night sweats. On the 13th of March, 1907, was detached and transferred to the Naval

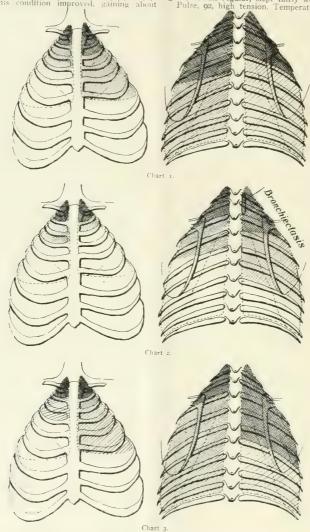

^{&#}x27;Dated July 18, 1908

Hospital, Mare Is'and, via the transport Dix. The chills, fever, and night sweats disappeared the second day out from Honolulu.

Arrived at the Mare Island Hospital March 30, 1907. In this hospital his condition improved, gaining about

*Personal history** Born July 23, 1877, at Lenox, Ia.

1907, while on the U. S. S. Indicna, at League Island, with a cold. Tubercle bacilli found in sputum about November 11, 1907; transferred to this hospital, received November 29, 1907. Smoked moderately and was an extremely moderate consumer of alcoholic stimulants.

Present condition Felt well and strong Appetite good;

CASE IV

During childhood had measles, no other sickness until after entering the service. Entered the service September

21, 1892.

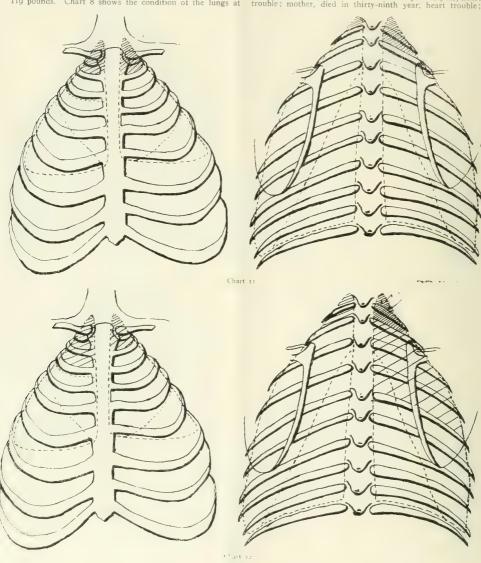

In 1897, while at the gunnery school, Washington, D. C., had typhoid fever; was in the Washington Hospital about two months; complete recovery.

Present trouble commenced in September or October,

slept well; bowels were slightly constipated. Coughed and siept well; bowels were sughtly constipated. Coughed and expectorated slightly in the morning. Had a sore throat, voice somewhat husky. Height, 5 feet 7½ inches. Normal weight, 145 pounds; present weight, 131 pounds. Pulse, 88. Temperature, 97.4° F. Respiration, 16. Chest circumference, 35.5 inches; inflated, 36.5 inches; deflated, 33 inches; expansion, 3.5 inches.

First physical examination, November 29, 1907. Chart 7 shows the condition of the lungs at this time. Tubercle bacilli were numerous. Other bacteria numerous. Third physical examination, July 13, 1908. Since admission this patient had progressively failed. Present weight, 119 pounds. Chart 8 shows the condition of the lungs at

Family history. Paternal grandfather, died in fiftieth year, Civil War effects; paternal grandmother, negative; maternal grandfather, died in seventy-second year, heart trouble; maternal grandmother, living, in excellent health, in eighty-second year; father, died in fifty-third year, heart trouble; mother, died in thirty-ninth year, heart trouble;

this time. Tubercle bacilli were numerous; other bacteria also numerous.

This patient did not take mercurial treatment.

CASE IV.—E. S. S., midshipman, third class, U. S. N.,
admitted March 16, 1908.

Nationality Paternal grandparents, Scotch; maternal
grandparents, Figli h

one brother, living, in good health; one sister, living, in

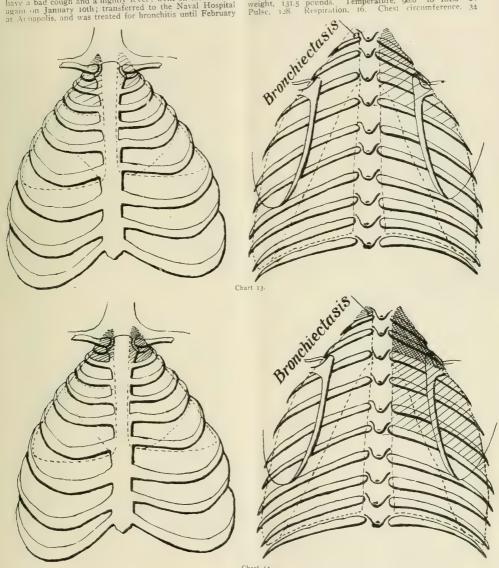

good health.

Personal history. Born March I, 1890, at Brooklyn, N. Y. Childhood diseases; measles; had tonsilitis and bronchitis when about seven years old; no other sickness until the present time.

Appointed to the U. S. Naval Academy September, 1906.

Present trouble commenced in December, 1907, while at the Naval Academy, with influenza; was on the sick list for four days; after leaving the hospital continued to have a bad cough and a nightly fever; went on the sick list again on January 10th; transferred to the Naval Hospital at Atnapolis, and was treated for bronchitis until February

well, bowels regular. Coughed and expectorated very little in the mornings. Had a slight hoarseness. Height, 5 feet 934 inches. Normal weight, 150 pounds; present weight, 131.5 pounds. Temperature, 98.6° to 101.6° F. Pulse, 128. Respiration, 16. Chest circumference, 34

died from heart disease. Personal history. Patient was born March 7, 1874, at Brooklyn, N. Y. Did not remember having any childhood diseases except chicken pox. Had pneumonia in his eighteenth year; had bronchial trouble in about his four-thicken pox.

teenth year. No other sickness before entering service. Entered service May 1, 1901, from Brooklyn, N. Y. Had malarial fever in Panama in 1903. No other sickness ex-

cept present trouble.

Present trouble commenced about October, 1906, while on duty at Newport News, Va., with weak stomach and general debility, and loss of weight. Had pains in chest, which he thought due to indigestion. Did not notice any cough until about middle of January, 1908, while on board the U.S. S. Minnesota, on cruise around South America. Was admitted to the sick list and transferred to the Relief, April I, 1908, and to Mare Island Hospital April 8th. His condition remained about the same except at the Mare Island Hospital, where his appetite improved and he gained about four pounds in weight. Was transferred to this hospital for tuberculosis. Received May 8th. Tubercle bacilli have been found in sputum. Habits: Does not smoke or drink.

Present condition. Patient felt fairly well; appetite fairly good, but could not eat very much on account of indigestion, which caused sour stomach and vomiting. Had palpitation of the heart after eating. Slept fairly well. Bowels were or the heart atter eating. Siept fairly well. Bowels were constipated. Did not cough very much, expectorated considerably from throat. Had pains in chest and between shoulders. Was troubled with sore throat and hoarseness. Height, 5 feet 7½ inches. Normfal weight, 146 pounds; present weight, 130½. Temperature, 98.2° F. at 10:20 a. m. Public 8.8. Perspectant.

Pulse, 84. Respiration, 16.

CASE X.—H. E. R., midshipman, fourth class, U. S. N., admitted May 16, 1908.

Grandparents, German.

Family history. Paternal grandfather, living in good health, in eighty-third year; paternal grandmother, died in eighty-seventh year, cause unknown; maternal grandfather, dead, age and cause unknown; maternal grandmother, living, in good health, in eightieth year; father, living, in good health, in forty-eight year; mother, living, in good health,

heath, in forty-eight year; mother, fiving, in good heath, in thirty-ninth year; no brothers or sisters.

Personal history. Patient was born July 6, 1888, at In dianapolis, Ind. During childhood had measles, chickenpox, and scarlet fever. Had smallpox in fourteenth year. Had pneumonia when he was about five or six years old. Had an attack of pleurisy soon after having pneumonia, and had another attack about two years ago. No other sickness before entering the academy

Entered the Naval Academy July 6, 1907. No sickness

after entering the academy except present trouble.

Present trouble commenced about the 12th of April, 1908. He went to sick quarters with a sprained knee. That night he took a bath, from which he caught cold, and had a temperature of 104° F.; was given ice bath and temperature reduced. Pneumonia was suspected, but did not develop, but he was attacked with a severe cough and had very mild night sweats for about a week. Sputum was examined and found positive. Was sent to the Annapolis Hospital and surveyed. While en route to this hospital he stopped at his home of Indhonopolis, Ind. While there he was examined by a specialist in tuberculous diseases, who pronounced his trouble pulmonary tuberculosis. Received at this hospital May 16, 1908. Had had catarrhal trouble since early childhood.

Habits: Smoked cigars very moderately. Did not drink

Present condition. Patient felt perfectly well; appetite fine; slept well; bowels regular. Had never had pains in chest. Coughed principally in the early morning and at night upon retiring. Expectorated very little.

Height, 5 feet 5 inches. Normal weight, 126 pounds; present weight, 12234. Temperature, 98° F. at 10 a. m Pulse, 104. Respiration, 20.

Chest circumference, 34% inches; chest inflated, 35½ inches; deflated, 32½ inches; expansion, 3 inches. Chart 21 shows the condition of the lungs at this time. Sputum examination showed very numerous tubercule bacilli. Placed on mercurial treatment May 18, 1908.

Second physical examination July 16, 1908. shows the marked improvement in the pulmonary lesions, and the condition of the lungs at this time. Sputum examination: Tubercle bacilli very numerous. Weight, 132

pounds. CASE XI .- R. R., ensign, U. S. Navy, admitted May

20, 1908.

Paternal grandparents, English descent; maternal grand-

parents, English descent

Family history. Paternal grandather, died as the result of wounds received in civil war; paternal grandmother, died in eighty-fourth year, cause unknown; maternal grandded in eighty-torin year, cause unknown; maternal grand-father, dead, age and cause unknown; maternal grand-mother, died in eighty-third year, cause unknown; father, living, in good health, in sixty-fifth year; mother, died from childbirth, in thirty-second year; three brothers, living, in good health; one brother died from acident; one sister died in infancy.

Personal history. Patient was born September 16, 1884, at Greenwich, Conn. No childhood diseases. Had measles in his fifteenth year. No other sickness before entering

the service

Entered the service September 29, 1900, from New Jersey. Was on the sick list twice while at the academy with ton-sillitis and once since graduation. No other sickness pre-vious to present trouble.

Present trouble commenced on the Galveston while at Vladivostock, Siberia, with severe cold lasting about two months. This was in December, 1907. In February he noticed sputum slightly tinged with blood, and examination of sputum for tubercle bacilli was positive. There was no loss of weight. Was surveyed March I, 1908, and sent to Mare Island Hospital. Was resurveyed and transferred to this hospital. Received May 19, 1908. While at Mare Island Hospital gained in weight, and general condition improved. Repeated examinations for tubercle bacilli were occasionally positive. Habits: Occasionally smoked a cigarette, drank moderately.

Present condition. Patient felt perfectly well; appetite very good; slept well; bowels regular. Had no pains in Coughed and expectorated very little.

Height, 5 feet 9 inches. Normal weight, 135 pounds: present weight, 134½. Temperature, 98° F. at 3 p. m. Pulse, 92. Respiration, 16.

Chest circumference, 331/2 inches; chest inflated, 353/4; detlated. 31½: expansion, 4¼.

Sputum examination showed a few tubercle bacilli present.

Chart 23 shows the condition of the lungs at this time. Placed upon mercurial treatment May 20, 1908.

Second physical examination July 17, 1908. Chart 24 shows the marked improvement in the pulmonary lesions, and the condition of the lungs at this time. Sputum examination: A few tubercle bacilli present.

Weight, 135½ pounds.

Case XII.—R. H. McL., formerly a lieutenant in the
U. S. Navy, admitted June 5, 1908.

U. S. Navy, admitted June 5, 1908.

Nationality. Paternal grandparents, Scotch; maternal grandparents. Irish.

Family history. Paternal and maternal grandparents, negative: father, killed in accident in fifty-ninth year; mother, died in thirty-seventh year, from pneumonia; one brother, living, in good health; one brother, dead, from consumption; one sister, living, in good health.

Personal history. Patient was born November 6, 1850, at Plainfield. N. J. Did not remember any childhood diseases, except scarlet fever. No other sickness before enter-

ing the service

Entered the Naval Academy June 22, 1868, from New ersey. Had typhoid pneumonia just after entering the Had pneumonia while on the European station in 1877. No other sickness while in the service. Resigned from the Navy in September, 1888. No sickness since leaving the service except present trouble. At the time of

resignation was lieutenant, senior grade.

Present trouble commenced in 1901 while at Washington, D. C., with cough and loss of weight (fifteen pounds). Went to Adirondacks, gained twenty pounds, and improved generally. About two months ago he visited a documentation. tor for local skin trouble; while there he mentioned about having a morning cough. The doctor examined a specimen of his sputum and found tubercle bacilli. Received at this

hospital June 5, 1908.

Habits: Did not smoke. Drank very moderately. Present condition. Patient felt well; appetite splendid; slept well; bowels regular. Coughed very little, principally

in the morning upon arising. Expectorated very little. Height, 5 feet 5½ inches. Normal weight, 135 pounds; present weight, 124 pounds. Temperature, 98.4° F. at 10 a. m. Pulse, 120. Respiration, 16.

Chest circumference, 363/4 inches; chest inflated, 381/8; deflated, 351/2; expansion, 2

Chart 25 shows the condition of the lungs at this time Sputum examination: Moderately numerous tubercle

bacilli present. Placed upon mercurial treatment June 8, 1908.

Second physical examination July 18, 1908. Chart 26 shows the improvement in the pulmonary lesions and the condition of the lungs at this time. Sputum examination: A few tubercle bacilli present. Weight, 141 pounds.

Of these patients Cases I and II have refused the mercury treatment, and are failing. The other ten are all receiving this treatment. Nine of them are improving, and one failing (Case V), and in this instance I believe the cause to be too much exercise.

All of our earlier patients reported as improved, continue to improve, and we have not had a single case show retrogression after improvement was first noted. We expect to be able to report several pa-

tients cured within a short time.

Whether these patients will require the continued administration of mercury over a long period of time is a question that time alone can decide, but from the statistics of cured cases during the past, it is only reasonable to suppose that they will remain well without further mercurial treatment. We began using mercury on January 17, 1908. During the three months ending March 31, 1908, our daily average of patients was sixty-two, and the deaths numbered seven, or a death rate of 11.29 per cent.

During the following three months ending June 30th, our daily average of patients was eighty-four, and the deaths numbered four, or a death rate of 4.76 per cent., a decrease in the death rate over the preceding quarter of nearly one half, or a reduction

of about forty-two per cent.

Of the four patients who died during this last quarter, one was in the hospital thirty-seven days. and had secondary ulcerative tuberculous lesions of the entire upper respiratory tract, and of the entire intestinal canal, with large excavations in both lungs, the immediate cause of death being intestinal perforation.

The second was in the hospital forty-five days, entire lung area involved, with large cavities in both lungs, secondary tuberculous ulcerations throughout upper air passages and entire intestinal tract. Tuberculosis of both kidneys and spleen. The heart showed extensive disease of the tricuspid, pulmonary and mitral valves. Immediate cause of death, intestinal perforation.

The third, a patient, of fifty-four years, was in the

hospital forty-one days, both lungs involved extensively, large cavities in the left, large aneurysm of the arch of the aorta, small spleen, weighing 45 grammes. This patient was tapped for abdominal ascites, and died on the table,

The fourth died after a lingering illness, with advanced pulmonary involvement, and serious secondary envolvement of various organs

Since the publication of my second report we have modified the procedure for the administration of mercury as follows: We now give an injection every other day until thirty injections have been given, then follow by a two weeks' course of potassium iodide, giving grammes 0.64 thrice a day, then one week's rest from medication, after which we resume the injections and repeat. This is giving us the most satisfactory results.

A table of weights showing gains and losses is herewith appended.

In my last report, May 25, 1908, Case II was included in the 30 per cent. failed, while Case IV appeared in the seventy per cent. improved.

embryo is being formed from it and upon it, as we shall see later. This substance is asexual; its existence is only temporary, and after it has fulfilled its functions it is finally destroyed by the embryo. This intermediary substance Dr. Beard called by various names: The trophoblast, phorozoon bearing animal, asexual generation, the larva. In a human being and in mammalia this substance is represented by the chorion. The first step then in the formation of an animal organism is the union between the male and the female elements. The newly formed cell divides and subdivides again and again, and the trophoblast is formed.

How then is the embryo formed? Upon the trophoblast develops an apical cell or the primitive germ cell. This apical germ cell divides a certain number of times, which is a fixed one for each species. These are the primary germ cells which are destined for future generations. It is not all of them, however, that unfold to form new embryos. As a rule only one does it. Should more than one unfold into an embryo, we have identical twins, trip-

lets, etc.

DR. BEARD'S THEORY IN THE CRUCIBLE OF

An Experimental Study of the Trypsin Treatment in Cancer.

By J. W. WEINSTEIN M D. New York,

United Veststant, Gastroenterological Division of the Vande Clinic; Attending Physician, Sydenham Hospital Dispensary

In presenting his unique theory on cancer to the medical profession, Dr. John Beard takes at once issue not only with the tenets of the medical science, but also with those of the embryological science as well. And he takes issue with the prevailing doctrines of the evolution of animal life from the very start. The prevailing idea of the evolution of a life cycle is that there is a union between the sperm and the ovum. After this union takes place cell division sets in, and from this an embryo is developed. This wonderfully simple mechanism is erroneous, according to the teachings and investigations of Dr. John Beard. He admits that there is a union between the sperm and ovum, and that as a result of this union mitosis sets in, but the division of these cells does not give rise to an embryo, but to something totally different, a substance which serves as an intermediary stage between the embryo and the zygote. This substance differs widely from the embryo. It is the progenitor of the sulmo as the

What is the fate of the rest of the primary cells? They travel along the germinal path and enter into the newly formed embryo and thus find shelter within the substance of their twin sister cell. They travel along and settle in various situations, but, strange enough, Dr. Beard has seen them in his microscopical slides to settle just in those localities. where cancer is so prevalent, as in the pyloric region of the stomach, about the rectum, within the lips, etc. The destinies of these vagrant germ cells vary. A good many of them degenerate and disappear. Others, however, persist; and they persist, according to the researches of Dr. Beard, with very base purposes, namely to destroy the life of their host, their own sister cell that has so kindly harbored them; as these are the future cancers.

Every primary germ cell in Dr. Beard's theory is endowed with unconscious memories to proliferate and go through a full life cycle. Some of the vagrant cells, after having entered the embryonic body, as we have seen before, degenerate, while others persist, and when occasion presents itself. they commence to repeat the life cycle. They have lost, however, during their migrations some of the unconscious memories and have retained others; moreover, they have assumed certain characteristics from the somatic cells, where they have lodged. And what is the result? A life eyele that is incomplete. An asexual generation alone is produced or a trophoblast. A cancer, therefore, is an irregular, irresponsible trophoblast; a life cycle with the asexual generation only, the embryo or the sexual part of

the cycle having been omitted.

We have seen that, according to the views of Dr. Beard, in every life cycle there are two generations, an asexual one, the trophoblast, and a sexual one. These two separate generations are seen both in plants and in animals. In plants the asexual generation being the more predominating factor of the two, while in animals it is just the reverse, the sexual generation being the more predominating. In the animal world the higher we ascend the scale of development, the smaller is the asexual generation, and in man it is reduced to the chorion.

The fate of the trophoblast is interesting. It keeps on growing in size at first, and then, after the embryo has developed from it and upon it, degenerative changes set in within the trophoblast or the asexual generation, while the embryo keeps on in-

creasing in size.

What are the factors that determine the decline of the trophoblast? This question has been puzzling Dr. Beard for a good while, until the discovery of the "critical period" came about, which discovery Dr. Beard considers as one of the most important both in embryological and medical sciences. It is through the discovery of the critical period that he found the key to his cancer cure. By the critical period Dr. Beard understands the era in the development of the embryo when the embryo first asserts its individuality, the time when the embryo starts first its own independent existence. By this time the embryo starts to feed itself by means of the allantoic placenta, and the pancreas commences to functionate. This period corresponds in the case of a human embryo to the seventh week of uterine gestation. Up to this time the digestion of the trophoblast and embryo is an intracellular, peptic one; after the critical period the pancreas starts to functionate, an alkaline digestion sets in, and this marks the decline of the trophoblast. The trophoblast ceases its further development and degenerative, atrophic changes set in, and thus its career is to an end. Should the embryo die before the critical period is reached, i. e., before the activity of the pancreas is established, the trophoblast, free of inhibition, will continue to grow indefinitely, thus mimicking cancer and producing malignant disease of the chorion. These latter facts form to the mind of Dr. Beard the chain of circumstantial evidence that the trophoblast is being destroyed by the ferments of the pancreas complete. And since cancer is an imitation of a trophoblast, hence it may also be destroyed by the pancreatic ferments. tumors, being composed of somatic tissue, are not affected by the pancreatic juice. As regards the mode of action of the pancreatic juice upon cancer. Dr. Beard believes that the trypsin of the pancreatic juice destroys the cancer albumin and the poisons generated by the cancer and discovered by Petry in 1899, and named by Beard malignin.

Having completed all these investigations, there was now only one thing left for Dr. Beard to do, namely, to apply the theory in practice. Not being a medical man, he tried his first experiments of

trypsin injections on the Jensen mouse tumor, and, according to his statements, the most wonderful results were derived. After several injections he found the cells of the Jensen mouse tumors degenerating, fading, and melting away. His triumph was complete. The grave cancer problem was solved.

Both the medical and embryological fraternities were loath to accept his views. Moreover, in the Middlesex Hospital a series of experiments with trypsin was made with negative results, and the new cancer cure was getting into disrepute. The leading medical journals had refused to publish Dr. Beard's articles and severely criticised them. Dr. Beard was in despair. He soon found, however, a champion of his theory in the personality of a former pupil of his, C. W. Saleeby, M. D., a writer of medical topics for laymen. In a series of publications in different periodicals, both in this country and in England, and finally in a separate publication. Dr. Saleeby has disseminated embryological and medical information among the public with the assurance that a positive cure for cancer has at last been found, a cure differing altogether from the former sure cures, and that the medical men would not give this wonderful discovery a chance. The public took the matter in their hands and they have compelled the medical profession to take the new cure more seriously. Stimulated, or rather forced, by these requests, medical men started to apply this new method of treating cancer in practice. Some cures were reported on one side; a good many failures on the other.

In order to test the efficacy of the treatment, the writer has experimented with trypsin in ten cases. All of these were carcinomata of the digestive organs. They were all clear, straightforward cases of cancer, without the shadow of a doubt as to the diagnosis. I append here a list of the cases without entering into the details of their histories:

M. B., male, sixty-two years old, carcinoma pylori.

J. K., male, fifty-eight years old, carcinoma cardire.

M. K., female, thirty-eight years old, palpable tumor along the greater curvature of the stomach.

E. P., male, sixty years old, carcinoma cardiæ.

H. S., male, sixty-five years old, carcinoma ventriculi et hepatis.

L. F., female, fifty-one years old, cancer of the lesser curvature.

N. T., male, fifty years old, carcinoma of the cardia.

A. K., female, fifty-eight years old, carcinoma ventriculi.

B. G., male, fifty-two years old, carcinoma of the pylorus.

L. F., male, fifty years old, carcinoma of the cardia.

All these cases were treated by subcutaneous injections of trypsin and anylopsin, according to the rules laid down by Dr. Beard and Dr. Saleeby. The idea of using amylopsin is because the trypsin, in acting on the cancer albumins, does not reduce them to harmless compounds; they are poisonous substances and the amylopsin digests them.

An antitoxine svringe is best used for the purpose. All aseptic precautions should be employed.

Preparation. The trypsin and amylopsin used by the writer were those prepared by Fairchild Bros. & Foster. This preparation has got the endorsement of Dr. Beard himself. It is a glycerin extract of the pancreas gland with some normal salt solution. It is dispensed in sealed ampoules, each containing about twenty minims of the extract.

Dosage and frequency of administration. I have injected daily and every other day, using twenty and forty minims per dose. Others have injected as high as 75 minims per day. I found, however, 40 minims not to absorb very readily. I used the amylopsin every third or fourth day. The contents of the ampoule is to be diluted with 2 to 3 volumes of sterile water. Messrs, Fairchild Bros, & Foster advise to start with an initial dosage of 5 to 10 minims, lest untoward symptoms should develop. In my last cases I have omitted this precaution and used 20 minims as an initial dose without meeting any ill effects. The injection is not very painful. There is no need for using cocaine.

Site of injection. It should be as near the tumor as possible, but not in the tumor tissue itself. Since the tumors that I dealt with were located in the epigastrium, I have found, however, this site a very unfavorable locality for the injection. For some reason or another the absorption in that part of the human anatomy proved very poor in my cases, and in one case (Case V) a big abscess formed. In several cases big lumps persisted for several weeks. I have found the buttocks to be the best site for injection. The injection should be made into the subcutaneous tissue, not in the muscle.

Untoward effects. Some aching of bones and backache. There have been described by others malaise, chills, etc., which I have not noticed in my patients.

Results. These were entirely negative. Six of these unfortunates had gone to whence nobody comes back; two are well under way in the same direction, and the other two were lost track of. I have not noticed any improvement in any of them. There were some periods of improvement and at times a temporary lull of symptoms, but these were no more than the natural, spontaneous ups and downs of any illness, irrespective of any method of treatment. The immediate cessation of the severe pain of cancer, which Dr. Saleeby so authoritatively speaks of, was not seen by me in a single instance. There is only one argument which Dr. Saleeby adduces in favor of the trypsin treatment which I may concede, and that is the powerful moral effect it has got on the mind of the patient. There is no doubt about it that when, to a man with a death sentence hanging over his head, hope to save his life is extended, the moral effect is very soothing and beneficent. But this is only temporary. As time goes on and the scales cruelly register the same continuous loss of flesh, the appetite gets poorer, the strength is going away, and the patient sees himself constantly going down hill with no gain whatsover, except some sores on his buttocks, he loses his courage and falls into the same hopeless state again.

Moreover, this fact alone should not justify us in using this plan of treatment. There is no need to import placebos from Edinburgh. We have got plenty of them on this continent.

Conclusion. I wish, therefore, in conclusion, to say that the trypsin cure has proved in my hands, after a series of careful trials and painstaking labors, a total failure, and, in my opinion, this new cure should be relegated to the vast legion of other sure cures for cancer that have preceded it, and that the cancer problem so far remains unsolved.

PROPERLY CONSTRUCTED FILTERING BEDS.

BY PAUL F. BUSSMAN, M. D., Buffalo, N. Y.

Filtering beds are constructed by placing conducting pipe, having broken joints, on the bottom of a reservoir of suitable size and covering the same with successive layers six inches or more in thickness; first of broken stone of large size, two inches, then stone of smaller size, one inch; upon this gravel, followed by coarse sand. On top of these several layers a bed of fine sharp sand is placed, having a depth of three, four, or five feet. The water to be filtered is placed on top of this bed of fine sharp sand and allowed to pass through to the underlying conducting pipe, to be carried to a reservoir or to the wells of a pumping station for final distribution. This is the universal construction of so called filtering beds; in reality, dirt catching beds. All the foreign matter held in suspension by the water is held, and the water that passes is secondary. Our filtering beds catch all the dirt which is not wanted and a limited amount of water, instead of obtaining all the pure water and none of the foreign matter in suspension. The man who constructed the first filtering bed made a mistake, and we followed his example ever since, spending millions upon millions of dollars catching dirt which we did not want. Instead of placing the filter in the water he placed the water in the filter, and we followed suit.

Now, if, instead of placing conducting pipe having broken joints on the bottom of a reservoir, we place them on the bottom of our river, lake, or whatever may be the source of our water supply, and cover the same in the same manner as described, all the pure water will pass to an unlimited amount and the foreign matter held in suspension will not be deposited on the filter, provided the flow through the filtering bed is not greater than the flow over the same. Foreign matter held in suspension in a liquid will follow the lines of least resistance. If for every million gallons of water used in a day a filtering bed of one acre in size was used, the flow through the filter would be at the rate of one yard a day. A body of water flowing at the rate of one mile a day would be a very slow natural current, still the flow would be one thousand seven hundred times faster over the filtering bed than through the same, and where this is the case there will be no deposit of foreign matter to clog the filter. By constructing a filtering bed one acre in extent for every million gallons of water required per day will enable all our cities located on our lakes and rivers to obtain an unlimited amount of pure water at a price no greater than that of merely pumping the same without considering the cost of installation.

Trusting that I am not mistaken in my proposition, I hope that it will prove a means of preventing the seed of many a disease to find a fertile ground in the economy of my fellow man.

495 JEFFERSON STREET.

OBSERVATIONS ON OPEN AIR TREATMENT.

By John Carling, M. D., New York.

Much has been said and written on the value of pure air in the treatment of tuberculosis, and while all are in accord as to the advantages derived from life in the open air, there is still a difference of opinion as to the best place to send certain patients. It is generally agreed that those suffering with pulmonary tuberculosis do better in a great altitude, while many contend that the sea shore is to be preferred when the bones and joints are affected. In England and on the Continent practically all hospitals for bone tuberculosis are located on the sea coast, but in this country opinion is more evenly divided, and many of those who formerly favored sea air are now opposed to it.

For tuberculous disease of the bones and joints an inland location has many advantages over the sea coast. We continue to send our pulmonary patients to high inland resorts, because we have learned that these patients breathe easier, feel more buoyant, and put on weight more quickly than when sent to the sea shore. Admitting that a maximum amount of pure air to the lungs is the main consideration in the treatment of bone tuberculosis as well as pulmonary, it follows that dry inland air, which encourages deep breathing, is to be preferred to the humid atmosphere of the sea shore.

Another important advantage is the matter of shade. Woodruff (1), of the army, has called our attention to the harmful effects of strong sunlight.

My own experience in the tropics, where the sunlight is intense, and my further observations on the effect of strong sunlight upon patients undergoing open air treatment, convince me that it is decidedly harmful. We are familiar with the feeling of discomfort and sometimes headache following prolonged exposure to the rays of the sun at the sea shore. If this is the effect on persons in robust health, how much more severe must it be in the case of debilitated children, many of whom have discharging sinuses, who are exposed to this glare daily for a period of several months.

It has been observed, moreover, in summer months, that those patients who are kept in darkened, but well ventilated, rooms during midday, and sleep out of doors at night, improve more rapidly than those who remain out continuously. The reason is obvious that much of the benefit derived by the latter patients from life in the open air is offset by their exposure to the strong sunlight. It is needless to say that moderate sunlight is not only not harmful, but desirable and necessary. When, however, it is strongly and steadily reflected from a glaring surface, its injurious effect on the patient's general and local condition soon becomes evident. Among whites this may be due in part to lack of protection from insufficient pigmentation, but I believe it is due more to the irritating action of light on the nervous system through eyestrain.

The firm nature of the soil is another reason for preferring the country to the sea shore in bone tuberculosis. The yielding nature of the sand at the sea shore, which makes locomotion difficult for children wearing apparatus, is a constant strain on the weakened and diseased joints. The sea shore is not contraindicated in all diseases of children. For rickets and cases of general malnutrition, where there is no actual disability, and sea bathing can be indulged in, a residence at the sea shore may be beneficial; but for bone and joint tuberculosis, as well as all other forms of tuberculosis, a dry inland climate is to be preferred.

Economy of administration and quality of food supply are factors which must be considered in the management of all hospitals. Sea side hospitals, because of the barren nature of the soil on which they are located, are compelled to go into the open market to purchase their articles of diet. Inland hospitals, on the other hand, are able to maintain their own farms, and not only supply a better quality of milk, eggs, vegetables, etc., but at a considerable saving in cost.

It is a well known fact that patients undergoing open air treatment do much better in winter than in summer. This may be due: I, To the diminished amount of strong sunlight; 2, to the cold air, which contains more oxygen than the warmer and more rarefied air of summer; and, 3, to the stimulating effect of the cold on the function of respiration, resulting in deeper and more frequent breathing, and consequently a greater supply of oxygen to the tissues. Not only do tuberculous patients do better in winter than in summer, but they need the treatment more. During the summer months the poor of the tenements may visit the parks and recreation piers and enjoy shorts trips to the country, but dur-

ing the winter months these privileges are denied them, and they are compelled to remain closeted in their ill ventilated rooms. Country homes and hospitals should therefore be kept open throughout the year, if possible, in order that patients may derive the benefit of continuous treatment until cured, instead of being returned to their homes in an improved condition, only to relapse during the follow-

In spite of the success met with in treating all classes of diseases with an abundance of pure air, our large city hospitals are doing practically nothing to give their patients the benefits of open air treatment. It is true that in a few instances attempts have been made to utilize the roof for such purposes, but the accommodations are inadequate and the results therefore unsatisfactory. In discussing the conditions prevailing in our city hospitals Thompson (2) says: "In the wretchedly ventilated wards the pneumonia patient, with a temperature of 105° F., sorely in need of fresh, cool air, lies in the next bed to the uræmic patient with a subnormal temperature, who needs warm air and a hot pack. The typhoid patient, with a racking headache and photophobia, lies facing a glare of sunlight, and the neurasthenic with insomnia is next to the patient with alcoholic cirrhosis and delirium In the surgical wards conditions are equally deplorable; septic and nonseptic cases are often crowded together in an atmosphere reeking with the odor of foul discharges. It may be said in extenuation that such overcrowding is unavoidable with the large number of patients and the limited amount of space. Admitting such to be the case, the remedy does not lie in erecting larger hospitals in the city, where the air at best is inferior, but in erecting them in the country. Every large city hospital should have its country branch, and for the city of New York no better location can be found than the high, unoccupied ground in the upper section of the Bronx and in Westchester County. This section, which lies between the Hudson River and Long Island Sound, is hilly, well wooded, and well drained, and covered with a network of trolley lines which make direct connections with those in the city. With a well equipped hospital car in charge of a member of the house staff, patients could be transferred from the city institution to the hospital in the country, not only without injury, but with every comfort. In this way the congestion, so evident in our city hospitals, could be avoided, and both medical and surgical cases placed under the best possible conditions for rapid recovery.

It is not at all improbable that the large hospitals of the future will be located in the country, and the present costly skyscraper buildings replaced by reception hospitals with observation and emergency wards, only. Objection to this plan may be made on the ground of inaccessibility, but it may be stated that as soon as the railway improvements now under way are completed this objection will be

largely overcome.

126 FAST THIRTS TOURTH STRITT,

HERNIA OF TUBE AND OVARY, COMPLICATED BY STRANGULATION OF INTESTINE.*

By C. F. KIVLIN, M. D., Troy, N. Y.

Ovary and tube hernia has been very completely reported by Dr. F. T. Andrews, of Chicago, who says: "It is the only gynæcological work preserved from Antiquity." The statistical review up to the present time, as far as I have been able to ascertain, gives but one hundred and three cases of inguinal hernia of tube and ovary. This may well be called an uncommon disease, if, indeed, not a rarity.

The ætiology of the disease differs in no particular from the ætiology of any inguinal hernia. It simply needs only the elements that go to make up any inguinal hernia with the particular influence which causes the tube and ovary to become engaged in

the internal or external ring.

Pathological anatomy does not differ in any essential from the pathological anatomy within the abdomen. The only disease of any consequence which has not been met within inguinal hernia of tube and ovary is carcinoma.

The following case came under my observation:

Mrs. D., age thirty-nine, U. S., housewife. Patient had had all the diseases of childhood; since then had been always well. Menstruated first at fourteen years of age, always regular, no pain, lasting three or four days, moderate amount. She married at eighteen years of age, and had four children, alive and well; oldest, sixteen; youngest, seven; one still birth, instrumental delivery.

Manual examination showed lacerated peringent first

Manual examination showed lacerated perinæum, first degree, bilateral laceration of the cervix, uterus anteflexed. General examination. Patient was extremely thin, nervous type, lungs normal, slight transitory murmur of heart. Slight amount of albumin in urine, kidneys were normal. Patient slept fairly well until present trouble commenced. Bowels were constipated. Small round tumor, size of English walnut, was found just to the upper and outer side of labia majoria, lying on the pubic bone. I thought at first it was a hernia and carefully examined it, but came to the diagnostic conclusion that it was a cystic benign

tumor of practically no pathological significance.

Present illness. I was called January 8, 1908, at midnight. Patient complained of intense pain in the upper abdomen, extending from the left hypocondriac region, directly across to the gallbladder. She vomited, suffered from shock; the pressure over the gallbladder gave intense

Diagnosis: Gallstones passing through the duct or ul-cerating through into the duodenum.

Next day and following days, symptoms of obstruction of the bowels appeared, which I thought was due to a large gallstone.

On Saturday, January 12, 1908, patient had two large movements of the bowels, which I accounted for by the gallstone being dislodged from duodenojejunal junction, and becoming lodged at the iliocæcal, but instead it must have been that the strangulation was temporarily relieved, allowing fæcal matter to pass on and later on becoming strangulated again.

On Sunday, January 13, 1908, nurse gave a high enema with some slight result. Monday, persistent vomiting; Tuesday, vomiting continuing. I told the people she was in desperate condition and the only hope was an operation, but could not promise good results. Patient was removed to the Troy Hospital, Tuesday, January 15, 1908, and operation was performed on the same day.

to the 1roy Hospital, Iuesday, January 15, 1908, and opera-tion was performed on the same day. Operation. Incision over the tumor; skin and superficial fat was incised, mass exposed, when I found I had to deal with a strangulated hernia. I then enlarged incision, so that the work could be done as rapidly as possible. Sac, distended with yellowish, black fluid, was opened, bowel had been caught and held firmly by the external ring.

^{*}Read before the Medical Society of Troy and Vicinity, February 4. 1008.

External ring was divided and the bowel, relieved of constriction, soon regained its normal color. Omentum, which was outside external ring, was ligated out, peeled off from the sac, and left exposed on the inner side of the sac; outside the external ring was seen the tube and ovary. Ovary was sclerotic and tube was conjested, due to constriction. Tube and ovary were returned to abdomen.

Operation was completed in the usual way with chromasized catgut for deeper layers, silk worm gut for skin. Diagnosis: Right tube and ovarian direct inguinal hernia complicated by strangulation of small bowels.

I have collected the following one hundred and three cases from the literature:

1826 FIFTH AVENUE.

A CASE OF ACTINOMYCOSIS OF THE PELVIS.* By Frank McMorrow, M. D.,

Syracuse, N. Y.

Actinomycosis is a rare disease in this country and in England, and is more prevalent in France and Germany. On this account certain phases of the subject are more readily studied by continental observers. Osler states that, although familiar with this affection in cattle since 1878, and constantly on the lookout for this disease, no instance has fallen under his personal observation.

It is an infectious disease, due to the presence in the tissues of a peculiar fungus termed actinomyces (ray fungus), and characterized by the development of tumor like masses, which readily undergo softening and suppuration, but which may easily extend into adjacent tissues. In man the disease was first described by James Israel, and subsequently Ponfick insisted upon the identity of the disease in man and cattle. The source from which the infected fungus is derived has not been determined, but it seems probable that it is taken in with the food.

In man this disease occurs most frequently in the lower jaw or in some tissues adjacent to the mouth. Of seventy-three cases reported by Moosbrügger, in forty-one the jaws, mouth, or throat were involved, in fourteen the respiratory tract, in eleven the intestines, and in the remaining seven the point of infection was not ascertained. In the intestines the disease may occur either as a primary or secondary affection.

Clinically this disease resembles certain forms of pulmonary tuberculosis and putrid bronchitis, and it may be mistaken for chronic pyæmia. Cases of human actinomycosis until recently were looked upon as sarcomata.

In looking over the literature of this subject, I find but very few cases of actinomycosis of the pelvis reported. Both Hacker and Sanger each report a case, Gildner reported a case with bilateral

*Read before the Social at Academy of Medicine, April 7, 1907.

actinomycosis of the ovaries with actinomycotic abscess of the left hip. There is one case recorded in the Lancet of actinomycosis in the lung of a boy sixteen years of age, followed by metastastic manifestations in the pelvis, one year afterward.

The sea of the season of the season of the season of

The following case of pelvic actinomycosis came under my observation and presents all the salient features of this disease:

CASE.—Mrs. S., of East Syracuse, born of American parents. She had always lived in this city, where her parents died at the ages of seventy-five and seventy-eight; parents died at the ages of seventy-nye and seventy-eight; one sister died during childbirth, and one was living. Three brothers were living, two had died, one as a result of an accident, the other of Bright's disease. She had always been strong and healthy up to the time of this sickness, usual weight 142 pounds. She was the mother of three healthy children, the youngest being five months and the weather weather the side. old when she was first taken sick. Her food was that usual in the families of working people.

Her personal history was that about the middle of October, 1905, while ironing one afternoon she was seized with cramps in the abdomen. She sent for the family physician and after being in bed for a day she was able to be about her work again. She had eaten some grapes that day and attributed her seizure in the abdomen to the fruit day and attributed her seizure in the abunding to the fruits she had taken; from this time on she noticed her health began to fail; she had occasional attacks of vomiting, which left her weaker each time; nothing that was done could check the progress of her malady. Since about the first of December she was confined to the bed continuously, with constant vomiting and general prostration.

I saw her first on December 26th. She was very much reduced in flesh with a marked cachexia. I called her attention to a lump in her side; she said she felt it, but as it gave her no pain or did not inconvenience her in any way she thought no more about it.

On December 29, 1905, patient was admitted to St. Joseph's Hospital in this city in a toxic condition. Dr. A. B. Miller saw her in consultation with me, temperature 101, pulse 120. She was very much prostrated and emaciated, vomiting still continued, bowels were very loose; at times she would be able to retain small amounts of animal broths and albumen water.

Physical examination: Patient was poorly nourished, cheeks were sunken, complexion sallow; there was some abdominal tenderness, a mass was plainly discernible just to the left of the umbilicus and one in left illac fossæ with areas which fluctuated on palpation. Liver and spleen were slightly enlarged. On vaginal examination a large

tumefaction was felt, the physical signs of which de-

noted a pelvic absces

The blood was examined; the red cells numbered 3,870,-000; white cells, 4.350. Hæmoglobin, 37 per cent. The uranalysis showed specific gravity, 1.010; trace of albumin, pus, and a few round cells.

The patient's condition remained the same for three or four days. Her temperature continued to fluctuate between 99° and 101.6° F. The vomiting still persisted, and there

was from six to eight watery stools in twenty-four hours.
On January 6th, her condition not having improved, Dr.
Miller opened the vaginal cul-de-sac and removed a large amount of fætid pus, containing minute yellowish granules, a culture of which was sent to Dr. H. S. Steensland, who promptly reported the inflammatory exudate taken from

the cul-de-sac to contain actinomyces.

the cul-de-sac to contain actinomyces.

The day following her temperature reached 102.6° F, and pulse 120; vomiting had ceased; in a few days the vomiting returned, less marked at first. Gradually she continued to fail, growing weaker and being unable to retain any nourishment by the stomach; she finally passed into a comatose condition, her temperature reaching 103. F. She died on the twenty-ninth day after entering the hospital.

The prominent features, then, of actinomycosis of the pelvis are: First: Gastrointestinal symptoms, persistent vomiting for over a period of two months. Where these symptoms are present, a physical examination then will reveal the pathological lesion.

Second: Fever. In the common forms of actinomycosis, which affects the jaw, with the swellings prominent and with elevation of temperature, the diagnosis is suspected especially if the patient has partaken of food from infected animals, but if a sporadic case occurs, with no enlargements and with a continued fever, typhoid is always looked for. In this case a blood examination will throw much light on the subject.

Third: The presence of an ill defined, slowly increasing swelling without pain, which may escape the attention of the patient and physician (there being no involvement of the lymphatics and no glandular enlargement until suppuration sets in), demonstrates the necessity of a careful examination in clearing the diagnosis in a hitherto obscure case.

The mode of infection here is doubtful, and it is more than possible that the lesion in the pelvis was secondary to the primary focus in the colon.

The question arises what would be likely to lead to a diagnosis in a single isolated case of this kind. The presence of tumor like masses slowly developing, especially in the neighborhood of the mouth, without pain, should be watched closely, and when suppuration sets in, free incisions, with a microscopical examination of the purulent discharges the

characteristic fungus will be shown.

Some writers believe that the disease is due to infection with two or more distinct species of microorganisms; this uncertainty about this subject has been increased by a tendency to class with actinomycosis certain other suppurative processes which have been called pseudotuberculosis or streptothrix infections. Professor Wright, of Harvard Medical School, in his essay which was awarded the Samuel D. Gross prize of the Philadelphia Academy of Surgery says: "The term actinomycosis should be restricted in its meaning to a suppurative process combined with granular tissue formation, the pus of which contains the characteristic granules." This definition, therefore, excludes those cases of so called pseudotuberculosis and streptothrix infections, because the microorganism of actinomycosis differs

entirely in its biological character from the microorganism associated with it.

The treatment of this class of patients is absolute extirpation of all infected tissues. When the disease is early recognized and the affected part is susceptible of thorough removal, a cure may be obtained. Actinomycosis, however, has a strong tendency to recur even after apparently thorough excision. Da Costa operated in a case of cutaneous actinomycosis twenty times before a cure was effected. Where the surgical procedure is limited. owing to the involvement of other organs, all fluctuating points should be incised, with the daily application of compresses containing iodine to the indurated zones; internally potassium iodide in large doses is valuable, with proper hygiene and life in

300 Snow Building.

Our Benders' Discussions.

A SERIES OF PRIZE ESSAYS.

Questions for discussion in this department are ar-nounced at frequent intervals. So far as they have been decided upon, the further questions are as follows: LXXVII—Hoge do you treat carriess ulcer? Closed

L.X.V II — I on the August 15, 1908.)
L.X.V III.—How do you treat acute coryza' (Answers due not later than September 15, 1908.)
L.X.I.X.—How do you treat sick headache? (Answers

due not later than October 15, 1908.)

Whoever answers one of these questions in the manner most satisfactory to the editors and their advisers will receive a prize of \$25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short; if practica-ble, no one answer to contain more than six hundred

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal The prize of \$25 for the best essay submitted in answer to question LXXVI has been awarded to Dr. Beverley Bedinger of Mar Verb when the

Robinson, of New York, whose article appears below.

PRIZE OUESTION LXXVI.

THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

BY BEVERLEY ROBINSON, M. D., New York.

Acute articular rheumatism is presumably, though not proved, a microbic infection. Over this infection the salicylates have greatest power-in lessening pain and at times diminishing intensity of the infection and also decreasing the liability to complications. They should be given in moderate doses and continued while manifest rheumatic symptoms last. Combined with an alkali in moderate proportions, preferably potassium citrate or sodium bicarbonate, they are more efficient and less liable to cause accidents, especially cardiac weak-

Personal experience, both hospital and private, makes me rely more upon salicin than any other of the salicyl compounds. It is antirrheumatic, almost specifically so; it is tonic; it is digestive; it causes no harm to the heart; it may be used with impunity for many days in large doses; it may be continued indefinitely almost, in moderate doses, with advantage to rheumatic symptoms of any nature. When salicin is not clearly useful, or remedial, after a few days' use, it is doubtful whether we have to do with acute articular rheumatism, or a multiple arthritis

of another prominence. Aside from the use of salicin, properly and continuously given, the most important indication is unquestionably rest, both to body and to mind, as far as may be. The bodily rest should be, of course, rest in a comfortable bed, with a moderately hard, well made hair mattress; and this rest in bed should be absolute until the fever has completely disappeared, and until pain and swelling of the joints are also gone. Again, there should be no voluntary movements so long as the heart shows evidence of endocarditis or pericarditis, but, above all, of marked, acute dilatation, manifested by physical examination and also by rational symptoms of rapidity, weakness, and irregularity of pulse, with more or less dyspnœa; or, on the contrary, by slowness, feebleness, and irregularity of pulse rhythm, and by pallor, or cyanosis of lips, face, and extremities, notably finger tips.

The greatest danger, present and future, of an attack of acute articular rheumatism, is the development of cardiac dilatation, accompanied or not by endocarditis or pericarditis. Dilatation of the heart can be prevented in two ways, and two ways only; first, insistence upon the use of salicin; second, absolute, prolonged rest in bed. Other complications which may arise, particularly pleurisy with serous effusion or empyema, should be treated by aspiration and drainage of the latter, avoiding, if possible, in these cases, resection of one or more ribs.

The affected joints may be treated locally by one of many liniments, or embrocations equally good. Linimentum saponis compositum, with or without equal parts of oil of turpentine, or Stokes's well known turpentine liniment, where oil of turpentine is combined with the yolk of egg and acetic acid, are, in my judgment, among the best, as shown by

long experience.

Moderate diet, especially during the acute stage, is important, and no meat, sauces, or highly spiced food should be allowed. A varied, very light, diet, however, is permissible, and I am confident that it is wrong and unintelligent to insist upon an absolute milk diet. Whenever milk is well digested and liked there is no positive objection to its use, but when it is objected to for one reason or another, light broths, jellies, rice in different forms, macaroni, eggs, cereals are unobjectionable. Whenever there is great temporary weakness from heart failure caused by excess of rheumatic poison and directly occasioned also by indiscretions of diet, overexertion, or sudden excitement, or anxiety, nothing quite equals the use of tincture of strophanthus by the mouth or hypodermically. Neither digitalis, strychnine, sparteine, camphor, caffeine, etc., can compare with it in rapidity and efficiency of action. The strophanthus may often be given with advantage at the same time as aromatic spirit of ammonia or the best

cognac. A small cup of hot, strong, palatable, well made coffee is also most useful.

The best available preparation of coca has been of signal value to me many, many times. Whenever the joints resist local applications and remain painful, and become distorted, a well padded, suitably applied splint is very essential to obtain best results. When after several days pain locally in the joint has subsided, proper resistant movements and massage treatment are of highest value. To keep bowels regular with Rochelle salts, as required, and the kidneys active with vichy are secondary indications, only a degree less important than what precedes to obtain best results in a given case.

As the rheumatic poison varies in intensity and in its effects with every individual, child or adult, so we must not hope to obtain equally good effects in every case, even from the most rational and best

ordered treatment.

Dr. William Lynn Wilson, of St. Joseph, Michigan, writes:

The patient should be put to bed in a large, airy room, free from all dampness, and into which plenty of sunshine enters. The temperature of the room should be kept at about 68° F. A competent nurse should be employed, who should have complete charge of the case, and have instructions to keep all others from the room, as even the closing of a door or a heavy step on the floor aggravates the patient's suffering. Absolute rest, both physical and mental, is the keynote of treatment; and this means confinement in bed from the first symptoms until convalescence is well established, and the danger of a relapse, or of cardiac complications, is at a minimum. The bed clothes should be soft and comfortable, and the patient should wear a soft flannel gown, open all the way down the front, and slit along the outer border of the sleeves, so that it can be changed with the least possible handling of the body. If sweating is profuse, he should lie between two light woolen blankets. The affected joints should be protected from the weight of the bed clothes by the latter being supported on a cradle, and each painful joint should be placed in the most comfortable position possible, and in many cases supported by a well padded splint.

When first called to a case, I usually give from two to five grains of calomel in divided doses, and follow with a glass of magnesium citrate. Afterwards the bowels should be moved with a saline laxative each morning, if necessary, preferably sodium phosphate, but if this not active enough, Rochelle salts, or one of the aperient mineral waters, should be given.

The diet for the first two weeks should consist mainly of milk, when it is well digested. In many cases it is well to dilute it with vichy water, and in some cases buttermilk should be substituted. Afterwards green vegetables and cereals may be added.

Water should be freely given, either plain, or in the form of lemonade, barley water, or oatmeal water. In the majority of cases the salicylates are the most useful remedies to reduce the fever, relieve the pain, and possibly shorten the attack. I prefer sodium salicylate made from oil of wintergreen, and give it in 15 grain doses every three

hours, until 90 to 120 grains are given in twentyfour hours. If at the end of forty-eight or seventytwo hours, the symptoms are not relieved by these doses, it is useless to continue the remedy, and I then replace it by acetphenetidin, 5 grains every three hours, either alone or combined with 1/4 to 1/2 grain of codeine sulphate. In some cases the pain is so severe that morphine sulphate, 1/4 grain, is required, given by the mouth or hypodermically; but it should not be resorted to until the salicylates alone have proved ineffective. Sodium salicylate is best given in capsules of $7\frac{1}{2}$ grains each, two of which are the ordinary dose, or in the following prescription:

R Sodii salicylatis, Ess. pepsin., Aquæ,

Sig.: A dessertspoonful every three hours.

If, at the end of forty-eight or seventy-two hours, the more severe symptoms are relieved by these doses I continue to give this drug in 71/2 grain doses, four times a day, until the acute symptoms have entirely subsided. Some patients cannot take the salicylates in large doses without producing distressing symptoms, as vertigo, nausea, vomiting, and even maniacal delirium. In these cases they may be given in smaller doses, and if they still disagree, they should be abandoned.

Sometimes aspirin in 15 grain doses is better borne, but this remedy also frequently irritates the stomach. Salophen, also in 15 grain doses, may be subtituted, but is more applicable to relieve the less acute symptoms. In the milder cases a capsule of acetphenetidin, 21/2 grains; salol, 21/2 grains; and codeine sulphate, 1/4 grain; or one of acetphenetidin and aspirin, each 3 grains, may be given every two hours; or oil of wintergreen, in doses of 10 to 20 drops, may be given in capsules, or in an emulsion. When their irritant effect on the stomach is the chief objection to the salicylates, they may be given for two or three days in an enema as follows:

| $\mathbf{P}_{\!\scriptscriptstyle{F}}$ | Sodii | salicylatis, | | | | | ٠ | | | | ٠ | ۰ | | | | 3p | -3i | , |
|--|--------|--------------|------|--|--|--|---|--|--|--|---|---|--|---|----|---------------|-----|----|
| | Tinct. | opii. deod., | | | | | | | | | | | | | | . 11 <u>k</u> | XV | ; |
| 3.1 | .\quæ, | | | | | | | | | | | | | 1 | 1) | to | 311 | j. |

and afterwards salicylic acid applied to the joints by inunction as follows:

| P, | Salicylic acid, Oil of turpentine. Lanolin, | | | āā 3i; |
|----|---|-------------|------|----------|
| М. | Lard, | • • • • • • | | āā 3jip. |

This is rubbed into the skin, and a dressing of absorbent cotton applied, and covered by some impervious material.

We may use equal parts of oil of wintergreen and

lanolin applied in the same way

Whenever inunctions are to be used we should

prescribe an animal fat for the base.

I have also used mesotan, diluted with a small amount of olive oil, and painted over the joints, and covered with a gauze dressing; but never with an impervious covering. In conjunction with the salicylate treatment, I give 30 grains of sodium or potassium bicarbonate every three hours, until the urine is rendered alkaline. I often give it in an effervescing solution with lemon juice. Afterwards

I continue one of these alkalis in smaller doses or substitute the effervescing potassium citrate in doses sufficient to keep the urine slightly alkaline.

In anæmic patients, or in old people, the alkalis should not be given. Instead of them tincture of ferrous chloride should be prescribed in 10 to 20 minim doses, well diluted, every three hours.

The administration of the salicylates and alkalis conjointly often proves too much for the patient's stomach, in which case their use should be curtailed, or the one most at fault abandoned.

In cases of hyperpyrexia we should use cold sponging or cold packs, and an ice cap to the head, until the temperature is reduced to 102.5° F. We may also use medicinal antipyretics cautiously.

In many cases of rheumatism all forms of internal medication sometimes prove useless, or even aggravate the patient's condition, in which event they should be discontinued, and reliance placed upon careful nursing and diet, soothing local applications, and absolute rest and quiet. When endocarditis is present or suspected a cold water coil, or an ice bag, should be placed over the præcordium. When the pericardium is involved, pain should be relieved by an opiate, and cold applications made as stated. If cold is not well borne, apply a mustard plaster or small blisters to the præcordial region. In children smaller doses of the salicylates are indicated, and potassium citrate in doses sufficient to keep the urine alkaline. Owing to the greater liability to cardiac complications in early life, the necessity of absolute rest, even in mild cases, should be particularly emphasized.

In the way of local treatment to the affected joints, in some cases enveloping them in absorbent cotton, and keeping them on a well padded splint, is sufficient. In more severe cases an alkaline lotion like Fuller's (sodium carbonate, 3vi; tincture of opium, 3i; glycerin, 3ii; water, 3ix), applied hot and frequently changed, is of great benefit.

When the redness and swelling are marked, an application kept wet with lead and opium solution is very helpful (tincture of opium, 3ii; diluted solution of lead subacetate, O.j). A bandage of several layers of gauze, saturated with alcohol and covered with rubber protective, often gives great relief.

I have also found that a saturated solution of magnesium sulphate applied on gauze and renewed as it evaporates is often useful. Sometimes the following ointment has a soothing effect:

| \mathbf{R} | Oil of gaultheria | 1 | | |
|--------------|-------------------|---|-------------------------------|-----|
| | Menthol, | | | |
| М | Lenolin, | | · · · · · · · · · · · · · · 3 | iv. |

In cases which permit of some handling of the affected joints, the following liniment may be gently rubbed in and applied:

| Ĭ, | Oil of gaultheria, |
|-----|------------------------|
| | Menthol, |
| | Tincture of opium, |
| | Liniment of soft soap, |
| 0.1 | |

After the more acute joint symptoms have subsided, an ointment of ichthyol, 25 to 50 per cent., is useful, and may be applied together with gentle massage, or the compound iodine ointment may be used in the same way.

To promote the absorption of exudates and effusions, massage and passive movements, and various hydriatic measures, as general and local hot baths, affusions, and douches, are all important. The alternate hot and cold douche is especially efficacious. The application of the negative pole of the galvanic current is an aid to absorption, while the positive pole may be used if the joints are still painful. When the inflammation and pain persist in one joint, the local hot air bath at a temperature of 200° to 250° F., given in one of the apparatus now on the market, is a very useful procedure. When skillful massage and hydrotherapy cannot be obtained, absorption of exudates and effusions can be hastened by three or four small blisters, applied within an inch of the affected part.

In some few cases in which the swelling and pain in a joint were very great I have used an ice bag with great relief; but do not resort to this method often, as there is a great prejudice on the part of the laity to cold applications in rheumatism.

The management of the stage of convalescence is equally as important as that of the acute attack, and all measures which tend to improve the patient's general condition, diminish the anæmia, and aid the nutritive processes should be employed, as tonics, iron, cod liver oil, etc. He should not be allowed to get up too soon. It is better to first sit up in bed for a short time, then in a chair, and then very gradually begin active movements. With a view to the prevention of relapses and recurrences his vasomotor reaction should be educated by various hydriatic measures, electric light baths, and massage.

Careful attention should be given to the mouth, throat, and nose, especially of the tonsils and pharyngeal space. If the tonsils are enlarged, or adenoids present, they should be removed as soon as possible. The importance of a daily evacuation of the bowels should be impressed upon the patient. The urine should be examined frequently, especially with reference to its acidity, excessive amounts of urates and phosphates and oxalates, and the presence of indican and the ethereal sulphates, in order that appropriate measures may be instituted. The diet should be carefully regulated according to the case. In the majority of cases milk, cereals, and the green vegetables constitute an appropriate diet. I usually allow meat once a day, eggs in moderation, fresh ripe fruits, and baked potato. Meat extracts, the coarser meats, sweets of all kinds, fried and made over dishes, pastry, and rich desserts should be prohibited.

The habit of drinking plenty of water between meals should be encouraged. In feeble anæmic patients the diet should not be restricted too much, and in the case of children oils and fats should be prescribed. The patient must be cautioned against exposure to cold and damp, especially when heated, and to avoid draughts. The clothing should be light but warm. Usually light, woolen underclothes are best, but he should be warned against the use of hot, bulky, woolen garments. Daily exercise in the open air should be advised.

the open air should be advised.

In all cases I regard the treatment of the patient as well as the disease to be most important, for there is a great and wide difference in the action of the respective measures prescribed among different patients, and constant watchfulness and caution are necessary on the part of the medical attendant.

Dr. James Porter Fiske, of New York, remarks:

Acute articular rheumatism, or rheumatic fever, resembles in many respects an infectious disease, and may be due to a streptococcic infection. It is characterized by fever, sweats, joint involvement, and often cardiac disturbance. The entrance of infection in some cases seems to be the tonsils, in others probably the intestinal tract. From the first the teeth, mouth, and throat should be treated to prevent further infection or reinfection; frequent hot antiseptic mouth washes for the teeth and mouth, Dobell's solution to the throat. If the throat is red and swollen frequent hot irrigations of normal salt solution are most helpful. Stomach and bowels should be put in order by use of calomel, grain ii, followed in six hours by Epsom salts. If the patient is seen early and the febrile onset is sharp, very little food should be allowed during first twenty-four hours. In these cases the joint involvement completes the diagnosis. In children under twelve the disease is often atypical, and we have observed cases in children with the febrile movement and later cardiac disturbance, without joint manifestations.

The observed ætiological factors are: I, Errors of digestion, including a depraved or hyperæmic condition of the digestive tract, often chronic constipation. 2, Exposure to cold, sudden change in temperature, chill, and tonsilitis. 3, The presence of some form of streptococci. At present the treatment is largely empirical, but frequently the disease is controlled, relapses avoided, and complications prevented. The real treatment will not be known until the proper bacteriological findings show us the ætiological factor. After that we may be given a curative serum.

Prophylaxis.—The gastrointestinal tract must be kept in order. Constipation, the most common disorder we have, must be avoided. The diet should be mixed and simple, avoiding overindulgence in starchy foods. Sweets and pastry should be avoided. Plenty of water between meals and systematic exercise are indicated. Wool or merino underwear should be worn throughout the year by the susceptible ones. Avoid exposure to cold. The nose and throat should be kept in a healthy condition. Large tonsils and adenoid growth should be removed. The teeth should be kept in good order. The feet must be kept warm at all times.

Treatment of the attack.—The patient should not be clothed in linen or rest between sheets. A light flannel wrapper should be worn, or the patient should lie between light blankets. The joints require protection. Cotton roll and flannel bandage will give support. Many joints require very careful protection, as twenty per cent. ichthyol ointment in lanolin with starch or plaster of Paris fixation. Later, on removal of dressings, the joint position should be changed and if necessary fixation reapplied. Some joints require gentle extension as well as fixation. The proper care of the joints in the severe cases will lead to less joint change, as well as great relief to patient. In acute articular

rheumatism the administration of the salicylates in many cases seems to be as effective as mercury in syphilis or quinine in malaria. In other cases, despite the treatment, the course of the disease is protracted. Certain cases indicate that the disease is a self limited one, going on to spontaneous cure, with, however, the liability to posttoxic conditions, and not infrequently the patient is left with a marked susceptibility. We recommend early in the disease the administration of calomel followed by an aperient. Then the free administration of salicylates in liquid form, say grain xv, every two to three hours, for twenty-four to forty-eight hours:

Sig.: Take one tablespoonful every three hours.

Give water freely, yet carefully; freely administer orange juice, and take good care of the skin. Change the bedding and bathing when possible. Every severely affected joint should be supported and placed at rest. Cardiac complications are best treated by occasional use of mustard locally with continued use of the ice coil. Hyperpyrexia is treated by the cool bath or rubbing the patient with ice. The diet during the febrile stage should be fluid, and consist of milk, peptonized or modified, simple broths, and gruels. As soon as convalescence is established it is well to place the patient on the following prescription:

 B
 Pulv. rhei.
 .5i;

 Sod. bicarb.,
 .7.
 .5i;

 Tr. nuc. vomicæ,
 .5ä;
 .5i;

 Ext. cascar, sagradæ,
 .5i;
 .5i;

 Sod. salicylatis,
 .3ii;
 .3i;

 Aq. menth. pip.,
 .q. s. ad. šiv.

Sig.: One teaspoonful after meals.

This familiar prescription may make some of the older clinicians smile, but it is potent in preventing relapses in susceptible patients who have suffered in the past.

(To be continued.)

Correspondence.

LETTER FROM LONDON.

The Funds of St. Bartholomew's Hospital.—Hospital Abuses. — Deaths Under Anæsthetics. — Ophthalmic Nursing.

London, August 11, 1908.

An appeal is being made to the public for fundon behalf of St. Bartholomew's Hospital. As this hospital is considered one of the richest in London, the appeal is rather surprising. As a matter of fact, it is only in the last few years that a deficit has arisen, and it has occurred under the following circumstances: Some time ago it became obvious to those in charge of the hospital's interests that it was being hampered by the want of several new buildings which had become absolutely necessary if thorough efficiency of work was to be maintained. But there were almost insuperable difficulties in the way

of expansion, owing to the fact that on every side except the south the hospital was bounded by public streets, and along the whole of the southern boundary was Christ's Hospital, or the Bluecoat School, as it is popularly called. The question of removing St. Bartholomew's Hospital into the country, or at any rate to some distance from its old site, was considered. A Mansion House committee of inquiry made an exhaustive investigation into the matter, and it was finally resolved that it was impossible in the public interest to entertain the idea of removing the hospital from its present site. So the governors of the institution took advantage of the removal of the Bluecoat School to acquire part of the site of that building for their extension scheme. This was done only after protracted negotiations involving Parliamentary proceedings. Eventually rather more than an acre and a half of land belonging to Christ's Hospital was acquired at a cost of £255,325. To obtain this large sum it was necessary to borrow £120,000, for which an interest of over £5,000 per annum has to be paid, and also to sell out stocks representing an income of £4,000 a year. These transactions obviously reduced the hospital's income by more than £9,000 a year. Previous to this there had been a surplus income of £2,000 a year. Now this has been turned into a deficit of £7,000 a year, and unless it is met this will soon accumulate into a very heavy burden of debt. Hence, in endeavoring to keep pace with the demands upon it, this institution has been forced from a position of comparative security to one of increasing dependence upon publie charity.

The growing feeling of British medical men against hospital competition was prominently shown at the annual meeting of the British Medical Association in Sheffield last week. For the first time in the history of the association was the question of hospitals dealt with, and a code was framed for the guidance of hospital committees under the title of "suggested model principles of hospital management." It was agreed that inability to pay for adequate treatment should be the consideration for the admission of all patients for hospital treatment. The system by which subscribers obtain letters which entitle patients to admission was condemned. An important discussion took place with reference to pay wards in hospitals, and by a large majority the resolution was passed that there was no objection to pay wards being connected with voluntary hospitals, provided they were open to all members of the medical profession, who should be paid any fee arranged for with the patient.

Another important resolution that was approved by a large majority was that all urgent and trivial cases, after the patients had been once seen, if deemed ineligible for further hospital treatment, should be referred elsewhere. With reference to the abuse of the out patient department, a resolution was passed that this department should be primarily intended for consultations.

The paying wards that have been established at St. Thomas's Hospital are very successful. They have been in use now for nearly two years, and represent an attempt to institute what is usually termed a hospital for the middle classes, that is to

say, one that affords comfortable accommodation with trained nursing and the attendance of a resident medical officer at a reasonable cost (which also includes medicines and dressings) and does not impose anything like such a burden upon patients of moderate incomes as would residence in a private nursing home. There is accommodation for nineteen men and twenty women, each patient having practically a separate room, and this arrangement insures complete privacy. Many of the patients are under the care of surgeons who are not connected with St. Thomas's Hospital.

The subject of deaths under anæsthetics came up for discussion in Parliament recently. A question was addressed to the Home Secretary asking for figures showing the number of deaths from anæsthetics in England and Wales during the last six years, and the following official figures were given: In 1901 there were 133 deaths from anæsthetics, in 1902 the number was 148, in 1903 it was 146, in 1904 it was 155, in 1905 it was also 155, in 1906 it was 183, a total for six years of 921. As regards the question of the appointment of a royal commission, Mr. Gladstone stated that he was in communication with the Lord President of the Council and through him with the General Medical Council on the question whether a course of instruction in the administration of anæsthetics could be included in all cases in the course of study required for the medical qualification. He thought the question of holding a formal inquiry by royal commission or committee could with advantage be postponed, at any rate until he knew what action the medical authorities were prepared to take in the matter. The Royal London Ophthalmic Hospital (Moor-

The Royal London Ophthalmic Hospital (Moorfields) has of late years gained a splendid reputation as a training school for nurses who intend to specialize in ophthalmic nursing, and for any nurse a certificate from Moorfields (gained after two years' work there) carries considerable weight whenever she applies for a post at a general hospital. This is well shown by the fact that, of the matrons recently appointed at the metropolitan hospitals, three have been at some time Sisters at Moorfields. A great compliment was recently paid to this training school when two of its nurses were specially selected to go to Philadelphia in order to teach the Moorfields system of ophthalmic nursing there.

Therapeutical Rotes.

Coal Tar in Chronic Eczema.—R. L. Sutton (Journal of the American Medical Association, August 8, 1908) calls attention to the value and efficiency of common coal tar, which may be obtained from any of the large roofing or paving companies, in the treatment of certain types of eczema. Applied undiluted on smooth pieces of cotton cloth, it relieves eruptions characterized by a dry, cracked and scaly skin where there is considerable papillary hypertrophy and but slight thickening of the outer layers of the epidermis. Eruptions of such a type are frequently seen about the knuckles, especially as a sequel to repeated attacks of an occupation derma-

titis. In these cases the author has found coal tar much superior to salicylic acid and similar keratolytics

Tincture of Eucalyptus in Hæmorrhage.-A. Todd-White (British Medical Journal, July 11, 1908) expresses the opinion that the value of the tincture of eucalyptus as a hæmostatic does not appear to be generally recognized. He has used it in minor operations, where the effects of adrenalin are transitory, and therefore dangerous, with good results. He cites the case of a patient who had a tooth extracted, and had had persistent hæmorrhage from the socket. The usual remedies were applied without avail. On the third day tincture of eucalyptus was applied, and the hæmorrhage almost immediately ceased. He has also found it effective in controlling bleeding from cuts of the extremities and from leech bites, after the other usual remediesalum, tincture of ferric chloride, ice, etc.—had failed. The tincture of eucalyptus is useful as a dressing on lint after circumcision or other minor operations. The author considers that the internal administration of calcium chloride, with the external application of tincture of eucalyptus, would arrest any form of hæmorrhage.

The Treatment of Trachoma.-In the Long Island Medical Journal for August, 1908, J. C. Hancock discusses the various methods of treating the symptoms of trachoma by medicinal applications. He has reached the conclusion that there are few diseases, local or general, in which a longer list of remedies has been employed; but the more he has seen of trachoma the more he has been convinced that any patient presenting objective symptoms sufficient to permit of a diagnosis is a case for operation. It is his belief that the only way to cure trachoma is to rupture the granules and express their contents, and to follow these procedures for a number of weeks with instillations of a mildly stimulating antiseptic, the last to eliminate traces of infection in a germicidal way and by absorption small and deep granules not affected in the operation. The instrument he prefers is the Jameson trachomatome, which does its work thoroughly, he says, without injury to the conjunctiva. He recommends that the eyelids should be subjected to a thorough squeezing after the operation in order to expel the contents of the granules.

The Treatment of Nervous Palpitation of the Heart.—Darié recommends (Journal de médecine de Paris, August 8th) the administration of the following combination in pill form, one pill to be taken with each meal:

B Pulverized valerian, ...
Extract of valerian, ...
Ammonium valerianate.

M et fae pil. No. xl.

Tonic Ferruginous Pills,—The following combination is credited to Erb in *Journal de médecine de Paris* for August 8th:

B Ferrous lactate,

Under Domestic Postage Rates, \$5; under Foreign Postage Rate, \$7; single copies, fifteen cents.

Remittances should be made by New York Exchange or post office or express money order payable to the A. R. Elliott Publishing Co., or by registered mail, as the publishers are not responsible for money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transportation through the mail as second class matter.

NEW YORK, SATURDAY, AUGUST 29, 1908. .

THE WEST HAVERSTRAW STATE COLONY.

The new State institution about to be provided near West Haverstraw, in Rockland County, some thirty miles from New York over the West Shore Railroad, should be a marked feature in the charity work of the State. During the first three years that the Craig Colony for Epileptics was in existence all patients admitted were personally selected by Dr. Charles S. Hoyt, for thirty-five years secretary of the State Board of Charities. The organic law at the Sonyea Colony declared that it should be for "the humane, curative, scientific, and economic care and treatment of epileptics exclusive of insane epileptics." Those who drafted that portion of the law governing the admission of patients inadvertently failed to exclude idiots and imbeciles, although it seemed plainly their intention to do so.

After Dr. Hoyt's work was over, and because of the enormous pressure that was constantly brought to bear upon the colony authorities to admit low grade epileptics, they were compelled to receive them. The cumulative result of this, some thirteen years later, is the presence of 600 of this class at Sonyea now, all of whom are absolutely hopeless of any degree of improvement or cure, and who improperly occupy space to the exclusion of patients of a better grade who might be benefited or cured. In 1904 the question of constructing in a remote part of these premises a building for 700 infirm epileptics demanding custody only was brought up

by Dr. Spratling. The plan was opposed by some who professed to see in it a perversion of the original design for which the colony was created-a view that was perfectly correct. Insistence upon providing such a building forced an important issue, for shortly after that an agreement was reached upon the necessity for a new institution, to be of great capacity and to be established near the most populous part of the State; the new place to be exclusively for the "overflow classes" from the large number of infirm inmates of the Craig Colony, the Institution for Feeble Minded Women at Newark, the one at Syracuse for children, and the Asylum for Unteachable Idiots at Rome, all of these having accumulated numbers whom their organic law had not intended they should provide for. All told, some 1,700 to-1.800 custodial cases have been counted as fit subjects for the new State Colony at West Haverstraw.

The legislature of 1907 authorized the governor to appoint a commission to select a site for the new institution in the "southeastern part of the State." Governor Hughes named a most excellent commission, consisting of the Hon. William R. Stewart, president of the State Board of Charities, Mr. Franklin B. Kirkbride, and Mr. Alexander Proudfit, all of New York city. This commission did its work in a singularly comprehensive and satisfactory manner. The illustrated report issued by it some time ago is without doubt the most complete document of the kind ever prepared by any similar commission in this or any other State. It was so complete, so convincing, that the legislature found it difficult not to act. The commission examined more than a score of sites within the area prescribed, and finally agreed upon a composite tract of some 2,000 acres, four miles from West Haverstraw, composed of cultivated fields, elevated plateaus that make fine building sites, and original forests containing an abundance of hard timber that will be more valuable years hence than it is now.

They employed well known landscape and sanitary engineers, caused a complete topographical map of the entire tract to be made, secured options on all the real estate wanted, and prepared and introduced into the legislature a bill making an appropriation of \$188,575 for the purchase of the property. An important point the commission did not neglect was that of an ample supply of pure water for all purposes. It had the great wisdom and settled determination to purchase 600 acres of elevated woodland containing fine springs and running streams, the conservation of the flow of which will give the new colony all the water it will ever require, and that, too, under a gravity system that will be moderate in cost. The legislature of the present year made an appropriation for the desired

purchase, and the governor promptly approved the bill.

The next step of the commission was to appoint an advisory committee of six-Dr. William P. Spratling, of Sonvea, chairman; Dr. L. P. Clark, of New York, secretary; Mr. Robert W. Hebberd, Commissioner of Charities, of New York; Mr. Homer Folks, secretary of the State Charities Aid Association, New York; Dr. W. E. Fernald, superintendent of the Massachusetts Institution for Feeble Minded Children, Waverly, and Mr. Alexander Johnston, of Fort Wayne, Ind. The commission spent three days in going over every part of the site and in making a thorough study of its physical advantages, with a view to advising upon the size and proper grouping of the several units of buildings for the different types of defectives which the new place is being designed to care for.

The committee was profoundly impressed with the natural and possible advantages of the place from every point of view. The State of New York, they feel, holds in its possession just now an opportunity for establishing one of the most necessary, best planned, best arranged, and most effective charitable institutions it is possible to conceive of. The topography of the site is such that a thousand or more defectives of a single class can easily be disposed in groups of buildings at one point on the property, and yet be so effectively isolated that other groups will be virtually ignorant of their presence. Nature has made provision for the most perfect natural classification. The next step will be to request the legislature of 1909 to make an ample appropriation for beginning the work on the colony. It would facilitate future work greatly if the legislature could be induced to make this first appropriation large enough to provide the needed central features at the outset-features which are usually provided piecemeal, because the early appropriations are rarely sufficient to permit of any other plan.

If the physicians of this State should feel so disposed, they might help materially by stimulating public interest in a charity destined to bring relief to families in all parts of the State. They can help secure a first appropriation of \$500,000, with which sum the necessary administrative group, a hospital, a power plant, heating plants, trade school buildings, ordinary schools, residences for officers and employees, an adequate sewage system that will keep flowing streams uncontaminated by toxic matters dangerous to health, and the construction of a water supply plant for the entire colony so far as a reservoir and the chief mains are concerned. All these could be provided in addition to a group of buildings sufficient for housing 800 to 1,000 defectives of a uniform kind. The authorities at the Craig Colony would hope to see Sonyea relieved as early as possibly of 600 infirm epileptics, that their places may be given over to others who hold out a promise of improvement or cure. It only remains for the Site Commission to have a perfect topographical map made of the entire property, and on it to plot the future homes and adjunct structures for 2,500 to 3,000 "children of the State," and for the coming board of managers to procure a medical superintendent who will be willing to give twentyfive years of hard labor to the making of a place whose future usefulness will be on a larger scale than that of any other charity in the State at present. Happily, not a whisper of bad politics has contaminated the new project so far, and we hope it may continue to escape the blight of an influence of this kind.

EXAMINATIONS IN CHEMISTRY.

It is of course natural for a man to look upon his own subject in a college curriculum as of great importance. His tendency to seek to impose his view upon others is apt to come out in undue prominence when it falls to his lot to arrange an examination paper. We recently quoted with approval certain criticisms of this tendency on the part of chemists, by Dr. Willis G. Tucker, professor of chemistry in the Albany Medical College. We are glad to find that another eminent teacher of chemistry, Professor Thorpe, of Manchester, England, entertains views which support Dr. Tucker's contentions. In the *British Medical Journal* for August 15th there is printed the following letter, signed by Professor Thorpe:

May I be permitted to draw attention to a question asked in a recent examination in organic chemistry for medical students, the syllabus for which states that "the whole subject is to be treated in an elementary manner"? The question was: "On analysis an acid, whose melting point was 190° C., gave the following results: 0.2159 gramme gave 0.3595 CO2 and 0.1209 H2O. On titrating with ammonia (1 c.cm. = 0.00334 NH₃) 0.4859 gramme of the acid required 37.52 c.cm. From these data calculate the molecular formula of the acid." Assuming that by the term "molecular formula" structural formula is meant-else why is the melting point given?-and assuming that the acid does not contain nitrogen, the empirical formula CoH+O+ agrees well with the data given. Of the many dibasic acids of this formula no one melts at 190°, the nearest being dimethylmalonic acid, which melts at 192°. But, apart from any slight error of this kind, is it to be expected that candidates, in a subject which is to be treated in an elementary manner (or so far as that goes in any manner whatever), and who may not consult books of reference during the examination, should be required to know the melting points of all the dibasic acids?

We have submitted this letter to an accomplished American chemist, and he writes to us: "I consider Professor Thorpe's criticism a most proper one. I should be at a loss to know how to begin to solve the problem as stated. Of what possible use such knowledge can be to a medical student I am unable to say." It is consoling to find that the extraordinary demands of medical examiners in chemistry are not confined to the United States, but the sooner they are resented everywhere the better.

THE INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Though this important congress does not begin its work for nearly a month yet, it is none too early for the physicians of the country to prepare in great numbers to take part in the proceedings, by their attendance if in no other way. The sessions are to open on September 21st and to continue until October 12th, but the section meetings will all be held during the week beginning on September 28th. The members are to be of two classes. Active members pay a fee of five dollars, and they receive, besides the ordinary privileges of membership, a full set of the published Transactions. Associate members pay a fee of two dollars. They are not entitled to the Transactions or to vote in the congress, but they receive the official badge and such printed matter as may be distributed during the sessions, they share in the entertainments, they may attend the meetings, clinics, demonstrations, etc., and they are entitled to the benefit of the special transportation and hotel rates which have been arranged for.

During the time to be devoted to the sessions of the sections there will be two general meetings. It is hoped that the President of the United States will preside over the first of these meetings, to be held on Monday, September 28th, and he has promised that, in case it is impracticable for him to do so, he will depute Secretary Cortelyou to represent him. The other general meeting will probably be held on Saturday, October 3d. Except on the days of these general meetings, each section will hold two sessions daily. Topics will be dealt with by the various sections as follows: Pathology and bacteriology (Section I, under the presidency of Dr. William H. Welch, of Baltimore); clinical study and therapeutics-sanatoria, hospitals, and dispensaries (Section II, under the presidency of Dr. Vincent Y. Bowditch, of Boston); surgery and orthopædics (Section III, under the presidency of Dr. Charles H. Mayo, of Rochester, Minn.); tuberculous disease in children (Section IV, under the presidency of Dr. Abraham Jacobi, of New York); the hygienic, social, industrial, and economic aspects (Section V. under the presidency of Mr. Edward T. Devine, of New York); state and municipal control (Section VI, under the presidency of Surgeon General Walter Wyman, of the United States Public Health and Marine Hospital Service); and tuberculous disease in animals and its relation to man (Section VII, under the presidency of Dr. Leonard Pearson, of Philadelphia).

About two thirds of the time allotted to the congress will be taken up with exhibitions. In connection with the congress, special lectures will be delivered in various cities by several of the distinguished foreign visitors. The cities in which these lectures will be delivered are Washington, Philadelphia, Boston, New York, and Baltimore. The lecturers are Dr. Bernard Bang, of Copenhagen (Washington, October 3d); Dr. A. Calmette, of Lille (Philadelphia, September 26th); Dr. Emil Coni, of Buenos Aires (Washington, October 2d); Dr. Arthur Newsholme, of Brighton (Washington, September 29th); Dr. Gotthold Pannwitz, of Berlin (Philadelphia, September 24th); Dr. R. W. Philip, of Edinburgh (Boston, October 6th); Dr. C. H. Sprouck, of Utrecht (Boston, October 7th); Dr. A. Martinez Vargas, of Barcelona (New York, October 9th); Dr. Theodore Williams, of London (Philadelphia, September 25th); Dr. Maurice Letulle and M. Augustin Rev. jointly (Washington, September 30th); Dr. L. Landouzy, of Paris (Baltimore, October 5th); Dr. A. A. Wladimiroff, of St. Petersburg (Washington, September 28th); and Professor N. P. Tendeloo, of Leyden (city and date not mentioned).

TUBERCULOUS DISEASE OF THE STOM-ACH.

We would call attention to the publication of the details of two cases of tuberculous disease of the stomach by Dr. R. Mouchet (Bulletin de l'Académie royale de médecine de Belgique. xxii, 3, 4). It is a rare affection. In Nothnagel's Encyclopædia, American edition, reference is made to twenty-one cases of this lesion collected from literature by Letorey, in 1895. Additional reports quoted in the volume bring the total number up to thirty-six cases. Osler refers to the rarity of the lesion. It is always associated with tuberculous foci in other organs, usually the lungs.

PILOCARPINE AND THE CONTENTS OF THE THORACIC DUCT.

The administration of pilocarpine is followed by an increase in the number of lymphocytes in the peripheral blood. Rous (Journal of Experimental Medicine, May), whose work on the lymphocytes we have already noted in these columns (New York Medical Journal, May 30th), finds that the increase of lymphocytes in the peripheral blood, fol-

lowing the intravenous injection of pilocarpine nitrate in dogs comes from the thoracic duct, and that quickened lymph flow and dyspnæa are accessory phenomena to the increased lymphocyte percentage. The action of pilocarpine is considered to be mechanical in the production of lymphocytosis, possibly in the form of direct pressure from contraction of smooth muscle. The experiments show the importance of the thoracic duct as a reservoir for lymphocytes and as a factor in the production of lymphocytosis, which is not, as is often asserted, due to direct migration of lymphocytes into the blood from the spleen, the bone marrow, and the lymph nodes.

Aews Items.

The New Jersey State Board of Pharmacy has issued registered assistant's licenses to fifty-three candidates, as a result of the July examinations

Naval Hospital at Newport, R. I .- The naval authorities of Newport have settled upon a site for the new Naval Hospital, for which an appropriation of \$85,000 is available.

Medical Society of the Missouri Valley .- This society will hold its twenty-first annual meeting on September 3d and 4th, at Council Bluffs, Ia., Dr. W. F. Milroy, of Omaha, presiding. Thirteen States are now represented in this society.

M. Henri Becquerel, the discoverer of the Becquerel rays, died in Paris on August 25th, aged fifty-six years. M. Becquerel held many positions in the scientific world, among others that of Permanent Secretary of the Paris Academy of Sciences.

Contagious Diseases in Chicago.—During the week ending August 15, 1908, the following cases of contagious diseases were reported to the Department of Health: Diphtheria, 41; scarlet fever, 35; measles, 19; whooping cough, 25; tuberculosis, 37; total, 181.

Robert Koch Foundation.—The Emperor of Germany has given \$24,000 to the Robert Koch Foundation, an institution to be opened at Berlin, for investigations in tubercu-The gift completes the \$100,000 which Andrew Carnegie stipulated should be subscribed before his promise of \$100,000 should become available

Medical Inspection of Schools in Buffalo.-The medical inspection of public and parochial schools in Buffalo will begin when the schools open on September 8th. Five doctors and one nurse have been appointed to conduct the inspection, namely: Dr. Shafer, Dr. Barrows, Dr. Wheeler, Dr. Callanan, Dr. McClure, and Miss O'Hara.

Floyd County, Ga., Medical Society.-At a meeting of this organization held on Saturday, August 22d, the evening was devoted to a discussion of the recent meeting of the American Medical Association and the Chicago post-graduate work. Dr. J. C. Watts and Dr. W. L. Funkhouser, secretary of the society, opened the discussion.

The Fort Worth, Tex., Medical College is planning to enlarge its scope by adding a department of dentistry. The establishment of a hospital to be maintained by the college, the city, and the county is under consideration, as the present hospital facilities of the college building are entirely inadequate, and when this new hospital is completed there will be sufficient space for the new department.

Meeting at Craig Colony, Dr. W. P. Spratling, medical superintendent of Craig Colony, has invited medical representative from all the State hospitals for the meane in this State and from the charitable institutions generally to meet at Sonyea on Thursday, September 3d. A medical programme has been arranged for the day, while the evening will be given up to entertainment. Dr. Spratling will lecture on the types of epilepsy, and show living pictures of epileptic manifestations.

A Young Folks' League for the Home Treatment of Tuberculosis has been organized in New York. The object of the league is to raise funds for the free distribution of milk and eggs to tuberculosis patients, and it hopes to cover the entire city, distributing daily three quarts of milk and six eggs to each patient who is properly recommended by the visiting nurse

The Mortality of Connecticut.—During the month of July, 1908, there were reported to the State Board of Health 1,487 deaths from all causes, which were 346 more than in June, 1908, and 31 less than in July, 1907. The annual death rate in 1,000 of population was 17.8 for the large towns, 15.3 for the small towns, and 17.3 for the whole State. Of the total number of deaths 158 were due to infectious diseases

The Mortality of San Francisco.-During the month of May, 1908, there were reported to the Health Department of the City and County of San Francisco 542 deaths from all causes, corresponding to an annual death rate of 12.48 in 1,000 of population, in an estimated population of 425,000. Of the total number of deaths 87 were of children under five years of age. There were 42 still births; 21 males, and 21 females.

German Hospital of Brooklyn .- During the month of July the hospital gave treatment to 115 charity cases, representing 1,530 days of treatment, while the balance, 135, pay patients, received 1,625 days of treatment, making a total of 3,155 days of hospital treatment; 89 emergency received first aid during the month and were discharged the same day. There were 79 operations during the month and the ambulance was sent out III times.

A Spa for North China.-We learn from the Lancet that in the Tangshun Hills in the Province of Shantung there are a number of hot and sulphurous springs, some of them being at a very high temperature. No definite analysis has yet been made of the waters of these springs, but some of them are known to contain large proportions of sulphur, saltpetre, and iron. It is proposed to erect modern hotels and residences at the place in order to take advantage of the medicinal properties of the waters,

A New Medical College in Atlanta, Ga.-The Hospital Medical College is the name of a new institution which will open for its first session on October 5th. The new will open for its first session on October 5tm. The new college is well equipped and will be conducted in connection with the Fields Hospital. A faculty of seventeen instructors has been appointed, and officers elected as follows: President, Dr. J. H. Powell; vice president, Dr. Giles Hathcock; dean, Dr. Charles H. Field; treasurer, Dr. J. R. Duvall; secretary, Dr. W. B. Lingo.

A New Hospital in Bayside, L. I., is soon to be established. Plans are being prepared, and it is said that the new institution will be thoroughly modern in construction and equipment. A stock company has been formed for the purpose of erecting and maintaining the hospital, and will be incorporated under the title of the Bayside Infirmary Company. A plot of ground on Broadway, overlooking Little Neck Bay, has been purchased for the site of the hospital, and it is expected that the building will be ready for occupancy in May.

A Campaign to Improve Health Conditions in Kentucky is being planned by the State Board of Health. the annual meeting of the board, which was held on August 21st, a resolution was passed authorizing an assessment on the membership of the board to defray the expenses of a commissioner to investigate the water conditions of the Ohio River and its tributaries. Dr. J. N. McCormack has been authorized to appoint the commissioner, who is to give his entire time to making the investigation. It is the opinion of the board that much of the sickness existing in the State is due to conditions prevailing in the Ohio Valley.

Women Medical Students in Swiss Universities. During the summer of 1908 there were matriculated at the several universities in Switzerland, 2,014 medical students, of whom 1,051 were women. Of the total number of students 530 were natives of Switzerland, and of these 33 were women. The number of women students at the several Swiss universities is as follows: Basel, 6 women out of a total of 172 students; Berne, 317 women out of a total of 512 students; Geneva, 266 women out of a total of 465 students; Lausanne, 216 women out of a total of 348 students, and Zurich, 246 serven out of a total of 517 . Personal.—Major Paul F. Straub, a surgeon in the Medical Corps of the United States Army, represented the Army at the Esperanto Congress held in Dresden recently. About 1.800 persons were present at the opening of the congress, and joined in singing an Esperanto hymn.

Lr. and Mrs. Addison Goodale, of Watertown, N. Y., celebrated the fiftieth anniversary of their marriage on

William G. Moorehouse, of Elmira, N. Y., has been appointed general medical examiner for the Pennsylvania

Scientific Society Meetings in Philadelphia for the Week Ending September 5, 1908:

WEDNESDAY, September 2d.—Association of Clinical Assistants, Wills Hospital.

THURSDAY, September 3d.—Obstetrical Society; Medical Society of the Southern Dispensary; Germantown Branch, Philadelphia County Medical Society.
FRIDAY, September 4th.—American Philosophical Society.
Medical Society.

Kensington Branch, Philadelphia County Medical

Local Epidemics.—There is a small epidemic of typhoid fever at Salem, N. J., fifteen cases having been reported in one week. There is a larger epidemic of typhoid fever in progress at Spring City, Pa., and at Royersford, Pa. More than one hundred and ten cases have been reported from these two places, and the Officials of the Penn-sylvania Department of Health have begun an investigation of the matter. Scarlet fever is epidemic at Collingswood, N. J., fourteen cases having been reported. Cerebrospinal meningitis is epidemic at Lewistown, Pa

Society Meetings for the Coming Week:

Tyesbay, September 1st.—Buffaio Academy of Medicine (Section in Surgery); Syracuse, N. Y., Academy of (Section in Surgery); Syracuse, N. Y., Academy of Medicine; Hudson County, N. FRIDAY, September 4th.-New York Microscopical Society.

The Mortality of Chicago.-During the week ending August 15, 1908, there were reported to the Department of Health of the City of Chicago 620 deaths from all causes, as compared with 657 for the previous week and 670 for the corresponding period in 1907. The annual death rate in 1,000 of population, in an estimated population of 2,166,-055, was 14.93. The principal causes of death were as follows: Apoplexy, 9; Bright's disease, 40; bronchitis, 4; consumption, 46; cancer, 25; convulsions, 2; diphtheria, 4; heart diseases, 63; influenza, 1; intestinal diseases, acute, to8; neasles, 2; nervous diseases. 11; pneumonia, 32; scarlet fever, 4; suicide, 7; typhoid fever, 7; violence (other than suicide), 42; whooping cough, 7; all other causes, 146.

Infectious Diseases in New York:

We are indebted to the Bureau of Records of the Department of Health for the following statement of new cases and deaths reported for the two weeks ending August

The Health of Philadelphia .- During the week ending August 15, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Typhoid fever, 50 cases, 6 deaths; scarlet fever, 24 cases, 2 deaths; chickenpox, 2 cases, 0 deaths; diphtheria, 33 cases, 5 deaths; cerebrospinal meningitis, 1 case, 1 death; measles, 26 cases, 2 deaths; whooping cough, 15 cases, 4 deaths; pulmonary tuberculosis, 116 cases, 44 deaths; pneumonia, 24 cases, 10 deaths; erysipelas, 1 case, 0 deaths; puerperal fever, 4 cases, 5 deaths; tetanus, 4 cases, 1 death; cancer,

20 cases, 23 deaths, mumps, 3 cases, 0 deaths. The following deaths were reported from other transmissible discases: Tuberculosis, other than that of the lungs. 8 deaths; dysentery, 3 deaths; cholera morbus, 2 deaths; diarrhœa and enteritis, under two years of age, 81 deaths. The total number of deaths from all causes was 449, in an estimated population of 1,532,738, corresponding to an annual death rate of 15.11 in 1,000 of population. The total infant mortality was 163; 147 under one year of age, and 16 between one and two years of age. There were 49 still births: 20 males and 29 females.

The New York Central Railroad's Emergency Hospital.-The officials of the railroad state that this hospital, which was established some months ago, has proved a decided success in every way. Between thirty and forty patients are received each month, and during the month of July there were 171 patients at the hospital, of whom 49 were new cases. Most of these patients were laborers who had been injured in the excavation. All patients received at the hospital are treated free of charge. The hospital is situated in the new building on the Lexington Avenue side of the Grand Central Depot, and is in charge of Dr. William Wells Sanford, who is assisted by Dr. McLeod and several nurses. Serious cases are sent to the Flower Hospital for treatment.

Charitable Bequests.—By the will of Levi Meyer, the Jewish Foster Home and Orphan Asylum, Philadelphia, receives \$6,000; the Jewish Hospital, Philadelphia, receives \$1,000; the United Hebrew Charities, Philadelphia, receives \$1,000, and the Pennsylvania Society to Protect Children from Cruelty and the Pennsylvania Hospital receive \$100

By the will of Sarah E. Ward, the Cullis Consumptives, Home, Boston, the Boston Home for Incurables, the Free Home for Aged Women, and the Boston Society for the Relief and Control of Tuberculosis become residuary

By the will of Catherine M. Sullivan, the Boston Home for Destitute Catholic Children, the Carney Hospital, and

the Little Sisters of the Poor each receive \$100.

By the will of Mrs. Margaret Kenney, the Consumptives Home, Boston, will receive \$100.

Vital Statistics of New York .- During the week ending August 15, 1908, there were reported to the Department of Health of the City of New York 1.334 deaths from all causes, 689 of which were in Manhattan, 104 in the Bronx. 424 in Brooklyn, 73 in Queens, and 44 in Richmond. annual death rate in 1,000 of population was 15.74 for the whole city, as compared with 20.16 for the corresponding boroughs was as follows: Brooklyn, 14.82; Manhattan, 15.67; Queens, 16.37; the Bronx, 16.56; Richmond, 29.93. Of the total number of deaths 559 were of children under five years of age, and of these 313 were due to diarrheal diseases. There were 160 deaths from pulmonary tuberculosis, III from organic heart diseases, 60 from Bright's disease, 79 from pneumonia, and 40 from contagious disdisease. 79 from picturous, and 40 from chargons are eases. One hundred violent deaths were reported, of which 5 were from sunstroke, 77 from accidents, 6 from homicide, and 12 from suicide. There were 654 marriages, 2,404 births, and 122 still births reported during the week.

The New Hospital for the Rockefeller Institute for Medical Research .- Plans have been filed for the main hospital building and isolation annex which are to be erected in connection with this institution. The main building will be a seven story structure of brick trimmed with Indiana limestone. In the basement will be examination rooms and servants' quarters. Reception rooms, dining rooms for the nurses and the hospital staff, a sitting room, and the general offices will occupy the first floor. The second floor will contain the living rooms of the staff; the third floor will contain rooms for patients; a department of floor will contain rooms for patients; a department of hydrotherapy will occupy the fourth floor; the diet kitchen will be on the fifth floor; on the sixth floor will be an x ray room; the seventh story will contain chemical laboratories, and on the roof will be an operating room, an etherizing room and a sterilizing ward. On all the four upper floors there will also be special rooms for patients. The isolation annex will be a two story building, connected with the main building by bridges of steel and stone. The estimated cost of the hospital is \$350,000, and of the isolation annex.

THE BOSTON MEDICAL AND SURGICAL JOURNAL August 20, 1908.

By John C. Munro. High Frequency Electricity in the Treatment of Car-diac Disease. By Horace D. Arnold,

Some Border Line Cases of Mental Deficiency, By C. C. Beckley,

The High Grade Mental Defectives, By W. N. BULLARD.

The Surgical Rights of the Public.-Munro observes that the public can feel that, taking American surgery as a whole, both that done by the masters and that done by the rank and file scattered over the length and breadth of this continent, there is no surgery in the world more intelligent, more skillful, and more considerate of the rights and feelings of the patient. The rate of advance is almost phenomenal. We in the States are wont to boast of our commercial progress, which is apparent to everybody. Few beyond those working in hospitals, laboratories, and medical libraries realize that the advance in our profession is parallel with that in our commerce. The advance in the one, however, is for the most part financial and scientific as applied to finance, while the advance in the other is scientific, humane, educational, and life saving. A significant quality that belongs to our profession is the generosity of the surgeons of one locality towards those of another in freely giving and receiving the good things that spring up in our art. It is a most refreshing sign of broad culture, and it does much to destroy the petty jealousies that are a heritage of past generations.

2. High Frequency Electricity in the Treatment of Cardiac Disease.—Arnold remarks that high frequency electricity may be so applied as to reduce the blood pressure in almost all cases. amount of the reduction is greater in proportion to the abnormal height of the pressure, although in his series of cases none have been above 200 mm. The greatest fall in the abnormal blood pressures was 40 mm., and the average fall was 17 mm. after an average treatment of 12 minutes. There after an average treatment of 12 minutes. is good reason to believe that there is also a favorable effect on metabolism, and that in this way the conditions that cause the high pressures are improved. For this reason the effect of the treatment is not merely temporary, but lasts for a considerable time. This form of treatment will be of special value in cardiac cases where the heart is having difficulty to overcome high blood pressure, especially in those cases where the pressure is due to faulty metabolism or poor elimination. This includes the important class of cardiorenal cases. It will also be useful as an adjunct in the treatment of those cases of high pressure which have not yet developed cardiorenal disease, which are due in part to our strenuous modern competitive life and our excessive ingestion of food.

- 2. Further Results in Suprarenal Transplantation.—Busch, Leonard, and Wright report a second series of suprarenal transplantations. In the first series of thirty-two cases a part of the animal's suprarenal was transplanted to its own kidney. At least one positive functional survival of such a graft was obtained. Partial proof of functionating suprarenal grafts was obtained in several other instances. The indication of successful transplantation consists in survival of the animal, in the absence of all suprarenal tissue, other than that of the graft, and in the histological demonstration of a living graft containing medullary cells. In the present series of thirty cases, transplantations have been made into the thyreoids, testes, and kidneys of dogs and rabbits, not only in the same animal, but also from one animal to another in the same species. The results of implantation into the testes and thyreoids were all negative. Positive results were obtained only in those cases where the kidney was used as the receiving tissue.
- 3. The Preservation of Anatomical Dissections with Permanent Color of Muscles, Vessels, Nerves, and Organs.-Souchon says that the following is a formula which is best suited for embalming subjects to be used in the dissecting room: A. Water, one and a half gallons; arsenious acid (saturated solution), one gallon; formalin, eight ounces. B. Alcohol, sixteen ounces; carbolic acid, eight ounces; creosote, two ounces; glycerin, sixteen ounces. B. and A. are to be mixed. The arteries are distended with cornstarch colored with crimson anilin, the diffusibility of which is regulated by a solution of tartar emetic. The formula used at Tulane for subjects for operative surgery he has worked out as follows: A. Arsenious acid (saturated solution), two and a half gallons; potassium nitrate, two pounds; formalin, four ounces. B. Alcohol, sixteen ounces; carbolic acid, eight ounces; creosote, two ounces; glycerin solution. B. is to be mixed with A.
- 5. Prominent Symptoms in the Diagnosis of Gastric and Duodenal Ulcers.-Graham remarks that all symptoms of gastric and duodenal ulcers are usually controlled by the measures directed toward pain. When pain is at its highest, so also is gas, eructation, and vomiting. By removing, neutralizing, or engaging the acid in the process of digestion, the pain stops, gas no longer forms, vomiting and eructation cease, and the patient enters a period of calm, to return to his former distress some time

later. The degree of discomfort depends on the extent of the lesion, the kind of food taken, and the care in its mastication. Until complications (obstruction, perforation, adhesions) have advanced, the pain and other symptoms seem chiefly due to increased acidity and spasm. Reverse gastric peristalsis adds to the discomfort. Later, when complications enter for consideration, the real symptoms are obscured, and the physician is often obliged to grope in the dark for an exact diagnosis, unless the patient has a judicial mind and can relate accurately his earlier symptoms. Again, the course of ulcer, like cancer, may be long latent, and be diagnosticated only when some threatening symptom like perforation suddenly prostrates the patient. If the perforation is not complete, or if only a small amount of septic material escapes, the pain may be of short duration, but intensely sharp and lancinating, simulating so closely gallstone colic that such diagnosis is the only logical one to make. If the perforation is free and the fluid septic or large in amount, the pain is much There is exmore intense than in gallstone colic. ceeding great shock, much morphine is required to control the symptoms, and early the appendicular region will be the centre of the pain. Later, if the patient survives, the pain will creep to the duodenum and gallbladder area. Unler such conditions one should think of perforating ulcer rather than gallstones or appendicitis. When, therefore, there are attacks of stomach trouble that run in continuous periods of days or months, with intermissions of days, weeks, or months with more or less freedom from symptoms, these periods recurring and occurring over years of time gradually deepening, the symptoms bearing close relation to food and being controlled or modified greatly by dietetic measures, food, drink, and alkalies, we may justly look for ulcer of the stomach or duodenum in a large number of cases. Purely functional overacidity may give symptoms difficult or impossible to distinguish from early ulcer. Appendicitis and more often cholecystitis may run a train of symptoms that will mislead the most painstaking clinician, but these cases are as purely surgical as are typical ulcer cases. Comprehensive surgery finds the source of the trouble and relief is the result. If a mistake is made it should be that of diagnosis only.

7. The Relation of Anticyclonic Weather to the Prevalence of Pneumonia.-Richter concludes that pneumonia is not merely a concomitant of the cold weather season. Its prevalence depends on anticyclonic weather, summer and winter, on the northern hemisphere, and not on low temperature. There is sufficient reason to assume that the quality of the air of an anticyclone changes in conformity with changes in the activity of the sun, and that the prevalence of influenza and pneumonia is subject to a specific quality of such air.

10. Experimental Parotitis.-Herb has made studies on parotitis. She obtained a diplococcus from the body of a man, about forty years old, who entered the hospital in a moribund condition and died in a few hours. The diplococcus corresponded in its essential characteristics to the organism obtained from mumps by others. Except the report that he had had mumps no history was obtained. The post mortem examination showed a right suppurative parotitis, bronchopneumonia, and sever l

The cerebrospinal, pleuritic, and minor lesions. pericardial fluids, bile, spleen, lung, testicle, and right parotid gland were examined bacteriologically. Cover glass preparations from the bile, pericardial. and cerebrospinal fluids showed a rather large diplococcus; the latter also contained a smaller coccus occurring in groups. The pleuritic fluid contained a short bacillus. They were both Gram positive. The Proteus vulgaris was isolated from the pleuritic, cerebrospinal, and pericardial fluids, the spleen, lung. testicle, and parotid gland; the Staphylococcus albus from the lung, testicle, cerebrospinal fluid, and parotid gland. From the lung, testicle, cerebrospinal and pericardial fluids, bile and parotid gland a coccus was isolated with the following characteristics: The coccus appeared most frequently as a diplococcus, occasionally in chains of 4 to 6 elements, or in small groups. It was round and measured from 0.5 to 0.8 micra when about twenty-four hours old. When several days old it measured from 0.6 to 1.5 micra. It was easily stained by all the ordinary anilin dyes and was Gram positive. It grew equally well aerobically and anaerobically. It was not motile, had no capsule or flagella, and did not form spores, gas, or indol. It grew best in a temperature of 37° C. A temperature of 50° C. for three minutes destroyed growth, cold inhibited but did not prevent growth when the culture was again placed under favorable conditions. Colonies developed from a milk culture two months old and from agar which was dried till it was broken. While the coccus developed on al! the ordinary media, its growth was characteristically slow, the colonies on a twenty-four hour glycerin agar culture being scarcely visible. She found by mixing sterilized saliva with agar, as in making blood agar, that an abundant growth could be obtained in from twelve to twenty-four hours. Ascitic agar was also a good medium. The organism was fatal to white mice, white rats, guinea pigs, and rabbits when injected subcutaneously or intraperitoneally. The animals usually succumbed within twentyfour hours of peritonitis. Those that survived for several days died of bacteriæmia. Inoculations of suspensions of the diplococcus into Steno's duct in the monkey and in the dog produced an acute, uniform enlargement of the parotid gland accompanied with slight fever. In the dog this enlargement was the result of an infiltration that consisted largely of mononuclear cells, and was accompanied with a general increase in the mononuclear cells in the blood as well as a distinct rise in the opsonic index with respect to the diplococcus.

Marriage from a Medical Viewpoint,

By CHARLES GREENE CUMSTON Omen, By B. S. TALMEY. 6. Notes on Sterility in Women,

1. The Appearance of Heteroplastic Tumors in the Transplantation of the Newgrowths of Animals. -Von Levden and Lewin remark that

it is quite probable that both the cancroid and the sarcoma which were observed in connection with the transplantation of an adenocarcinoma of a rat were caused by some irritative influence the nature of which we do not as yet know, originating from the proliferating cells of the primary newgrowth. With these observations we have before us the fact of the appearance of new tumors, not alone the continuation of the growth of a transplanted portion of another tumor. We are therefore in a position to cause experimentally the development of a new formation, and this may give us the important opportunity to study the appearances and the growth of such a tumor from its very inception. Of course, the significance of such work for the questions involved in the study of cancer cannot now be estimated. One thing, however, must be kept in view: The principal reason for opposing the parasitic theory of the causation of cancer has been the statement that in the experimental studies of cancer new tumors were not produced in the animals but simply metastases of the original growth were artificially produced. Hauser, who is a determined opponent of the parasitic theory, has stated that the successful transplantation of tumors could be interpreted in support of the parasitic nature of the disease only when the tissues of the animal experimented upon could be made to undergo carcinomatous changes by the transplantation of the cancer cells into that animal. Such a phenomenon would happen in his estimation if the epithelial elements of the animal's skin showed carcinomatous proliferation after the subcutaneous inoculation of cancer cells into that animal. These conditions, which Orth also accepts as the criteria of a true infection, have in fact been fulfilled in the tumors observed by von Leyden and Lewin. The skin of the animals experimented upon has been stimulated in such a fashion that carcinomatous overgrowth has taken place in its elements. The fact is important that the phenomenon observed in the tumors of mice by Ehrlich, Apolant, Loeb, Liepman, and Bashford, the stimulation of the connective tissue to sarcomatous change by the inoculation of cancer cells into an animal, has been seen by von Levden and Lewin in another animal, the rat.

3. Medical Treatment of Appendicitis .- Cruikshank states that a few cases of appendicitis can be treated successfully by operation only; others are best treated by this means, but the great majority of cases are amenable to nonoperative treatment, no food or purgation, rest, judicious use of morphine, ice bag or hot applications, and Fowler's position. Enormous numbers of healthy appendices are removed. An operation should not be done during the acute stage. The mortality from appendicitis operations in the hands of incompetent surgeons is absolutely frightful. If there is doubt whether to operate or not,-don't. Every expert operator is not a surgeon, the former possesses merely dexterity, and the latter wisdom. The former works for various reasons, and the latter for the comfort and longevity of his patient

5. Marriage from a Medical Viewpoint.—Cum ston observes that matrimonial life in the case of neurotics is a very frequent cause of an improvement in neurasthenia, the result of overwork, of

poor hygiene, melancholia, and certain trifling mental disturbances produced by over fatigue, on account of the regularity that it brings to all the acts of life. Latent hysteria should not be considered as a serious hindrance to marriage, but it, nevertheless, is well to ascertain all points relating to the pathological antecedents of the future wife. Recent statistics show that the number of gynæcological operations necessitated by gonococcic lesions increases every year. To a certain extent the public has surmised the dangers accruing from this disease, but not to the extent that it should. In face of the terrible consequences to which gonorrhea may give rise, the mortal dangers to which the spouse is exposed, sterility following gonococcic complications, certain members of the profession have declared open war against gonorrhœal subjects guilty of contamination. In Germany especially a law is under consideration which tends to protect women against venereal contagion from the husband, or even the lover. Professor Hegar, in Germany, and Jullien, Cazalis, and several other physicians in France, have proposed an obligatory verification as to the genital innocuity of the future husband. As a conclusion to this Cumston would advise that young men be told that, if they are unfortunate enough to contract gonorrhæa or syphilis. they should loyally consult a reputable physician before their marriage to ascertain whether or not they are fit subjects for matrimony. It is high time that the profession put an end to public ignorance in these matters, and thus to a great extent avoid many catastrophies and moral pain.

6. Notes on Sterility in Women.-Talmey speaks of sterility in women. The primary sterility, when no conception has ever taken place, can be idiopathic sterility, absolute and irremediable, absence of vagina, rudimentary uterus, absence oi tubes, absence or degeneration of ovaries; or rela tive, which is curable. Secondary sterility occurs when there was fύundation, but an abortion has taken place or the child died, and after the first conception the woman ceases to propagate. In sterility caused by a diseased condition of the internal genital organs electricity is, according to Talmey, if not the only remedy, the remedy par excellence. physiological effects of the electric current take place by virtue of the vital properties of the body through its action on the nerve supply, influence upon circulation, secretory and excretory processes, and the acceleration and absorption of morbid products. Electricity promotes the nerve tone, increases mus cular activity, and quickens circulation. When the current passes through living tissues the interpolar action of the positive pole is, by contracting the capillaries, anodyne sedative, anticongestive, denutritive, and antihæmorrhagic. The interpolar action of the negative pole is, by increasing the blood supply, stimulating, congestive, derivative, and alternative, thus favoring absorption. The physiological effects of the faradic current are mainly mechanical, producing a veritable interstitial massage. These physiological qualities make electricity the best remedial agent in the treatment of endometritis, metritis, salpingitis, ovaritis, and pelviperitonitis. Endometritis and pelviperitonitis are by far the most frequent causes of sterility. The electric current tends to give to the uterus a certain amount of tone which it requires to harbor the ovum to the end of its de velopment.

10. The Importance of Learning a Trade in the Army,
By W. V. SINCLAIR

r. Headache.-Harris has elaborated the following anatomical classification of headache, on which he bases the appropriate treatment. A. Superficial. I. Diseases of the brain coverings. (a) Scalp-for example, cellulitis; weight of hat or mass of hair. (b) Pericranium-e. g., rheumatic. (c) Bone-e. g., tuberculous or syphilitic caries. The brain substance itself seems to be insensitive to ordinary stimuli, and the actual mechanism of the production of the pain in headaches is mainly by means of painful stimuli to the nerves supplying the coverings of the brain and its vessels. In group I the nerves of the scalp, pericranium or bone carry the painful impressions to the sensory centres. 2. Reflex visceral neuralgias of scalp. Ocular, dental, pulmonary, cardiac, gastric, etc. group the morbid process affects the nerves of a viscus at a distance, such as the branches of the fifth nerve from chronic strain, or from iritis or glau-The painful stimuli reach the Gasserian ganglion and set up irritability-so that other areas supplied by the fifth nerve become tender and appear to be the source of the pain. This is a true reflex visceral neuralgia. B. Deep. 3. Reflex cortical neuralgia. Visual "academy" headache; thunder storm; neurasthenic. Of the causes of headache within the cranial cavity, the true neuralgic headaches, such as the neurasthenic or that produced by dazzling the eyes, emotion, a thunder storm, etc., are probably true neuralgia of the cortical sensory centres and are best relieved by rest and antineuralgic remedies. 4. Toxæmic constipation and sluggish liver; influenza and other fevers; foul air; alcohol, ether. This is a very important group of headaches, but the exact mechanism of the production of the pain is obscure. In some instances, as in fever, increased vascular turgescence probably plays a considerable part. Alcohol and ether headaches may also be due to arterial engorgement. Constipation and sluggish liver are well known causes of headache, which may be periodic and accompanied by vomiting. 5. Increased intracranial pressure. This

is the most important cause of headache, and produces the most severe and persistent pain. In cerebral tumor there is general increase of pressure from the growth, and the headache is apt to be dif-When the cortex membranes are involved, then the pain becomes localized, and is a sign of the utmost localising value. Meningitis causes severe headache in two ways-first by involvement of the nerve endings in the meninges, and secondly by increased intracranial pressure due to cedema of the cortex. In acute or serous meningitis there is a rise of pressure due to the excess of cerebrospinal fluid. The same is true in hydrocephalus. Headache in cerebral syphilis is often most intense; even large doses of mercury and iodides do not bring relief until the cedema of the brain and excess of cerebrospinal fluid, due to the meningitis, have subsided. In arteriosclerosis from contracted granular kidney severe headache is common and is usually vertical or occipital. Both in this condition and in chlorosis (anæmia) there is cerebral œdema, raising the intracranial pressure. Nitroglycerin is the drug that here gives the quickest and most relief. Intolerable headache, optic neuritis, convulsions, coma, and death may be produced by a loose fibroma in the lateral ventricle, acting as a plug and preventing the escape of cerebrospinal fluid. True migraine is the most important and commonest of the causes of periodical headache, and the writer holds that the severe pain in the head is due to raising of the intracranial pressure. The hemianopia, dimness of vision, the numbness in the tongue, cheek, or arm, and the temporary aphasia, are all suggestive of sudden arterial constriction in the cortex. The vomiting is also a most characteristic sign of elevation of the intracranial pressure. Antineuralgic remedies only do good by their depressant effect, and for that large doses are required. Local measures would be trephining and opening the dura; lumbar puncture; leeches to the scalp; fomentations, hot bottles, or ice bag to the scalp or neck. Indirect measures, by lowering the general blood pressure-nitroglycerin and the nitrites; cardiac depressants, such as opium. aconite, chloral, phenacetin, and other coal tar analgesics. Purgation, diaphoresis, and hot baths.

2. Diminished Cardiac Dulness in Cancer .-Gordon finds that in many cases of cancer there is a decided diminution of the cardiac dulness in the recumbent posture, which is often of value in diagnosis. All cardiac dulnesses under two inches wide he considers as diminished. Three possible explanations may be advanced: (a) It is possible that in a case of cancer the heart, like other muscles, may become more flaccid than normal and less well filled than in health. If so, it may fall away more from the chest wall than normal in recumbency. (b) It is possible that the lungs may lose some of their elasticity in cases of cancer, and a spurious emphysema result which may partially obliterate the cardiac dulness. (c) In many cases of cancer the heart is known to become much reduced in size.

4. Dangers of the Calmette Reaction .- Butler considers that the Calmette ophthalmoreaction is often deceptive and may do grave damage to the eve, and that it is not justifiable to use it any longer. He has abandoned it, using in its stead injections of

old tuberculin (P. G.) as a diagnostic measure. He reports three cases in which, as the result of the installation of tuberculin, a typically tuberculous process was set up in a perfectly healthy eye.

1. Intrathoracic Growths.—Glynn states that the symptoms of intrathoracic growths or hypertrophy of the bronchial glands are largely due to pressure on, or invasion of, nerves, bronchi, vessels, and other structures in the mediastinum. As a rule, the more extensive the tumor, the more positive the symptoms. Pain is usually present, in most cases neuralgic in character, and described shooting, burning, or stabbing, intermittent, or more or less continuous with exacerbations. The seat of the suffering is the back and sides. Pain is usually absent or slight in lymphadenoma or Hodgkin's disease. Dyspnœa is frequently present when the tracheobranchial glands are enlarged or are the seat of growths, and is commonly due to constriction of the lower end of the trachea; it may also be due to implication of the pneumogastric or recurrent laryngeal nerves, to pressure on the bloodvessels, or on the auricles, to changes in the lung following bronchial obstruction, or to pleuritic effusion. The dyspnæa may at times be paroxysmal. Hoarseness is a common symptom in mediastinal tumors and arises from pressure on the pneumogastric or recurrent laryngeal nerves. Cough is present at some period; it may be constant or paroxysmal, weak or very noisy. When a vocal cord is paralyzed there is also stridor. More or less fever is present in the subjects of Hodgkin's and malignant disease. The earliest indication of slight bronchial compression is lessening of the vocal fremitus, with successive diminution in vocal resonance, respiratory murmur, and chest expansion. In the cases of malignant disease, probably originating in the thymus or its remains, the physical signs in many respects closely simulate those of aneurysm. The diagnosis of mediastinal tumor is often difficult. In ancurysm there is apt to be more or less bulging, with expansile pulsation, single or double murmurs, diastolic shock, and tracheal tugging. On the other hand, a dull area with absence of heart or breath sounds, the existence of enlarged glands in the lower part of the neck, or the history of an operation for such glands, would be in favor of growth. Passive congestion and cedema of the head, neck, and arms, and also pleural effusion, are more common in growth than in aneurysm. Evidence of arteroll concepts at a lustom of suplidis or of could

tions likely to cause excessive strain, would tell in favor of aneurysm; youth or the female sex in the direction of growth. The prognosis of mediastinal growths is necessarily unfavorable. In the enlargement of the mediastinal glands associated with Hodgkin's disease, arsenic in increasing doses is indicated. In the rare cases of syphilitic infection of the mediastinal glands iodide of potash should be given. With these exceptions treatment can only be palliative.

2. Human and Cattle Tuberculosis.-Overland has studied the occurrence of tuberculosis in men and cattle on ninety-seven Norwegian farms, with especial reference as to whether it is rare or frequent for cattle and men to infect each other. He found, first, that tuberculosis in man and tuberculosis in cattle have a certain relation, as the tuberculin reaction in cattle on farms where there has been human tuberculosis occurs nearly three times as frequently as on farms where the disease was not Many circumstances favor the belief that animals and man can infect each other with tuberculosis. In districts where tuberculosis in the cattle does not exist, there is found less tuberculosis in the inhabitants. In animals only those living in captivity or kept as domestic animals develop tuberculosis spontaneously. Wild animals are free from the disease. It is therefore evident that man and cattle must be regarded as the seat of the tuberculous virus, but the "human" and "bovine" types have no doubt a common origin, and their difference is but relative. It is agreed that the human tubercle bacillus is less virulent to cattle than to man, and vice versa. But bacilli from man can cause tuberculosis in cattle; also they increase their virulence on successive passages till they at last have the same virulence as the cattle bacillus. All our live stock in the country ought to be tuberculin tested more than was the case before we fed our children on unboiled milk. 3. Appendicular Abscess.—Cuff suggests that

the operative treatment of appendicular abscess should conform as much as possible to the following propositions. The abdominal route should be chosen in all cases. The incision should be so placed as to allow of the easiest access to the origin of the mischief, and it should be so large and so capable of extension that any conditions likely to be found may be dealt with easily and thoroughly. Ease of manipulation means quickness of operation, and this quickness is essential in dealing with these half poisoned patients. A second operation should not be necessary if it can possibly be avoided, hence the appendix should always be removed at the same There should be as little mutilation as is time. compatible with thoroughness, two incisions not being made when one, properly placed, at first, will do all that is necessary. Drainage tubes, both in size and in number, should be reduced to a minimum. It should always be borne in mind that tubes leave very weak places in the scar, as well as being liable to injure the peritonæum, and so predispose to intestinal obstruction from the formation of adhesions with the bowels. Injury to the nerve supply and to mucular fibres should be avoided when possible, and the wound and its resulting scar should be placed in as strong a part of the abdominal wall as is compatible with the foregoing requirements.

Anæmia from Anhæmatopoiesis, By C. Aubertin.

Anæmia from Anhæmatopoiesis. - Aubertin says that in the majority of cases of serious anæmia anhæmatopoiesis is not anatomically demonstrable, and there is usually if not always the destruction of the blood which is related to deglobulisation. That is to say in most cases of anæmia the study of the anhæmatopoiesis should not lead one to forget the investigation of the causes of the anæmia, the mechanism of the destruction of the blood globules. which is of great importance from both the pathogenic and therapeutic points of view.

- Hæmolysin in Human Pancreatic Juice .-Wohlgemuth states that in inactive human pancre-

- atic juice there is no hæmolysis, although it possesses marked lipolytic properties. If rendered active by the addition of enterokinasis or calcium chloride, or by prolonged standing, the juice attains the ability to disolve red blood corpuscles under certain conditions. If an inactive juice is mixed with lecithin alone, this suffices to make it hæmolytic without developing tryptic properties. The appearance of the hæmolysis is to be ascribed to the lecithin The mechanism of the action of the formation. hæmolysin in any case is that the trypsin become active, immediately separate lecithin from any combination of lecithin and albumin, the lecithin completes the hæmolytic amboceptor of the pancreatic juice (lipase), and thus the hæmolytic lecithin is produced. But as long as the nature of the pancreatic hæmolysis is not clearer than it is to-day the possibility must be borne in mind that we have to deal with the action of a completely independent factor, perhaps with a combination of lipolytic and tryptic actions.
- 3. Periarteritis Nodosa.-Hart reports a case of this disease, and believes that it is to be ascribed to a general infectious toxic cause and not to a spe-
- Complement Joining Tuberculous Anti-5. bodies and Their Relations to the Tuberculin Reaction.—Cohn says that antituberculin is not an antitoxine in the usual sense and has nothing to do with agglutinins. In seven sera containing antituberculin agglutinin was demonstrable in only one, while on the other hand Koch's agglutination fluid was precipitated in nine sera that did not contain antituberculin, which therefore contained tuberculous agglutinin, but not the complement joining antibodies.

of Opsonins, 2. Opsonin.—Böhme gives the following résumé of his conclusions. I. The opsonic value of the serum opposed to typhoid bacilli is well shown by the use of thinned active serum. With regard to the faults of method and the varying action of different normal sera conclusions can be drawn only from many observations. 2. In a typhoid patient observed for a long time there was a marked increase of the opsonins during convalescence. In spite of the high opsonic value a recurrence took place. After sinking at first the opsonic value again became high during the further course of the recurrence. Several weeks after the fall of the fever it fell to normal. 3. The inactive sera of three convalescents from typhoid fever showed a notably increased opsonic action, but one which was decidedly less than that of the active serum. They were markedly increased by the addition of normal active serum even to the same height as that shown by the active serum of the patient. 4. The increase of opsonic action in the cases observed thus depends upon an increase of thermostabile substances. 5. A marked increase of the opsonic action through the addition of thinned active serum is shown in inactive sera of typhoid fever patients and in sera produced by active immunisation against typhoid bacilli, colon bacilli, and meningococci. 6. The reactivity of the inactive serum, as well as a number of other peculiarities, can be explained best by the theory of an amboceptor complementlike construction of the opsonins of active sera. 7. The phagocytosis brought to a standstill under the influence of the serum may be greatly increased by constant shaking. 8. A rapid dissolution of the typhoid bacilli within the phagocytes takes place only in the presence of active serum. 9. The normal cerebrospinal fluid contains only traces of complement and opsonin.

3. Lumbar Anæsthesia in Abdominal Operations. Holzbach asserts that in lumbar anæs thesia during abdominal operations there is absolute absence of pain on the part of the patient during the entire duration of the operation, the production of conditions in the field of operation which facilitate the technique as far as possible in favor of a rapid and unobjectionable performance of the operation, the reduction of danger from the anæsthetic to a minimum both during and after the operation, the prevention of unpleasant or doubtful sensations at the beginning and in consequence of the anæsthesia, and the slightest possible influence upon

the postoperative course 4. Periodical Acetonæmia in Large Children.-Hecker reports six cases of acetonæmia met with in children between the ages of three and eleven. Two The patients were brothers. The prominent symptom is vomiting, and it has been suggested that the tongerma bug by be the ward. If the inamition caused by the vomiting. Hecker does not agree with this view, but considers it unquestionable that the primary condition is not the vomiting, but the formation of aceton bodies, and that the vomiting is a result of this disturbance, probably a symptom of excretion.

5. Demonstration of Blood in the Urine .-Schumm mentions three different forms of spectroscopes as especially fitted for the detection of blood in the urine. Unchanged oxyhæmoglobin may be detected in the urine when present in the proportion of 0.004 per cent., about one drop in the daily quantity of urine, by the direct spectroscopical examination without previous preparation, when the urine is examined in a layer about 20 cm. thick. The tannin method is suitable for cases in which, aside from the spectroscope, only the simplest laboratory aids are provided. The limit of its sensitiveness is about 1 in 5,000 or 0.02 per cent. The coagulation method is complicated and uncertain with small quantities of blood. The zinc acetate method may be simplified by performing the necessary heating over an open flame. The technique is fairly simple. With 50 to 100 c.c. of urine its limit of sensitiveness is about I in 20000, 0.005 per cent. If the hæmoglobin in the urine is not unchanged, but is in the form of methæmoglobin or hæmatin, and if the quantity is small, it must be taken from the urine in a suitable way in order that the spectroscopical test may be successful. In the application of the different spectroscopical chemical procedures one must remember that the symptom of absorption of the hæmochromogen formed from the hæmatin is not constant. The absorption bands begin within a few minutes after the addition of the reducing agent. The layer of ether over the watery ammoniacal fluid is necessary in order to prevent too quick oxidation of the hæmochromogen by the oxygen of the air. The principal bands suffice to identify the specrum of hæmochromogen.

8. Menthol Poisoning.—Schwenkenbecher describes the symptoms produced by the ingestion of eight or nine grammes of menthol in three men experimentally, one of them being the relator himself. The results of the experiment lead him to the conclusion that too large doses should not be used in

the internal administration of this drug.

The Symptoms and Condition of the Blood in Per By J. G. TAYLOR пистоп Апапча,

1h Combition of the Ginns in Measle By F. E. TYLECOTE

1. Remarks on the Diagnosis of Iliac Swellings. Battle thinks diagnosis is not advanced by those who divide all abdominal conditions into those which require operation and those which get well without operation, and he has no great admiration for those who hesitate to express an opinion as to the nature of an abdominal swelling "until the cloth has been lifted." He excludes from consideration osteosarcomata, sarcomata of the abdominal wall, enlargements of iliac glands, aneurysms, and abscesses due to careous disease of the bones, or disease of the sacroiliac joint. The first question to be asked as to a swelling of slow growth is, is it inflammatory, is it subsiding or advancing? If not inflammatory, is it cystic or solid, simple or malignant? Does it originate from the iliac fossa, or has it extended from a neighboring organ? Three groups of swellings are considered, (1) those which arise from the iliac fossa, (2) those which extend into it from below, (3) those which invade it from above. In the first class are (1) fæcal accumulations, (2) enterospasm, (3) intussusception, (4) glandular enlargement, (5) ureteral distension, (6) new growths of the large bowel, (7) inflammatory swellings, (8) hyperplastic tuberculosis of the cæcum, (9) actinomycosis. In the second class are (1) pyosalpinx, (2) hæmatocele of the broad ligament, (3) ovarian tumors. In the third class are (1) enlargements of the gall bladder, (2) movable kidney, (3) hydronephrosis, pyonephrosis, and growths of the kidney, (4) malignant disease of the colon or sigmoid flexure.

3. The Surgical Treatment of the Incompletely Descended Testis. — Rawling observes that when this condition applies to one organ the condition should be watched until the seventh year of life, after which an operation should be performed if descent has not occurred. The cremasteric fibres and other restraining bands having been exposed and divided, and the peritoneal process removed. the possibility of scrotal placement can be determined. If this should seem impossible, the testis should be removed. In cases of double incomplete descent, double abdominal replacement has been advocated, the hernial protrusion being thus cured and the canal closed. The author dissents from this view for the following reasons: .1. The abdominally replaced organs will almost certainly lose their spermatogenetic power. 2. The inguinal, pubic, and puboscrotal organs will retain spermatogenetic power in about half the cases until the age of thirty to forty, the inguinal testis retaining this power longer than the pubic, or high, puboscrotal varieties. Operation is therefore advised prior to puberty, the canal being exposed, the testis delivered, and the hernia cured. If this course seems inadvisable, it is better to allow the testes to remain in the inguinal

4. Some Experiments in the Treatment and Prevention of Infection in Enteric Fever.—Gordon gives the following summary: 1. Medical Izal oil is an efficient germicide in vitro for bacilli of the colityphoid group. 2. It can be given in large doses, in emulsion, without ill effects, for a long period. 3. It does not disturb the appetite and is well tolerated after two or three doses. 4. It does not increase peristalsis and checks diarrhea. 5. It is diuretic and diaphoretic, and increases the elimination of toxines. 6. It causes disappearance of bacilli of the colityphoid group, and if given for a sufficient period

the organisms will not reappear. 7. This germicidal effect upon the urine does not follow the use of other antiseptics which are usually given in enteric fever. 8. In the author's experience mortality was diminished by this treatment, and the course of the disease was favorable, especially in the acute stage. 9. Favorable results occurred even in cases in which Izal oil was not given until the second week of the disease, and in a series from which all mild cases were eliminated.

5. A Review of Some Recent Work in Gynæcology.-Playfair reports the following results of Carmichael's experiments on rabbits: 1. The entire ovary of the rabbit may be transplanted successfully. 2. In eighty per cent. of the cases there is partial degeneration of the ovary. 3. The ovary may undergo either fibrous or cystic degeneration. 4. The Graafian follicles and ova persist and mature for several months after the grafting process was performed, but ultimately tend to become cystic. 5. The germinal epithelium persists in a small percentage of cases. The conclusions from these experiments with reference to the human subject are as follows: 1. It is unlikely that the entire human ovary can be grafted with success. 2. Part of the ovary may ovulate and perform its function of internal secretion. 3. Partial grafting will usually give the most satisfying results, especially when the cortical portion of the organ is employed for that

8. Major Operations in the Treatment of Puerperal Sepsis.—Taylor states that the operations proposed for this condition are hysterectomy, ligature of pelvic veins for thrombosis, and abdominal or vaginal section for puerperal peritonitis. As to hysterectomy, as Cumston says, there are no absolute clinical signs which will enable one to proceed with certainty. Most of the operations have resulted fatally; the exceptions are possibly those which would have recovered without operation. Ligature, excision, or removal of the contents of thrombosed pelvic veins was proposed by Sippel in 1894 and has been carried out by several operators. Sinclair's opinion is reasonable that abdominal section and complicated manipulation in the pelvis will seldom be justifiable. If anything is done it should be of a conservative nature like colpotomy. Abdominal or vaginal section for puerperal peritonitis has a more hopeful outlook. About half of the reported cases have resulted in recovery.

Proceedings of Societies.

MEDICAL ASSOCIATION OF THE GREATER CITY
OF NEW YORK

Special Meeting for the Borough of Queens. Held in Long Island City, April 6, 1908. Dr. Nen. Orrin Firen in the Chair.

Personal Observations in Scarlet Fever.—This paper, by Dr. Charles G. Kerley, will be published.

Dr. R. E. VAN GIESON said that after an experience of over forty years the impression which was most prominent in his mind in regard to scarlet fever was that the disease varied very greatly in

severity and as regarded concomitant symptoms. Sometimes the epidemics were so mild that in many instances the parents, not recognizing the disease, thought it unnecessary to call in a physician for the slight illness observed. Consequently, the children were soon allowed to go about as usual, and it was only later, when they had dropsy from the scarlatinal nephritis, that medical attendance was summoned and the true nature of the affection made known. In other epidemics the type of the disease was fulminating and the mortality appalling. Thus, it had been his melancholy experience to see a whole village depopulated of its children, many of whom died of cerebral involvement before the eruption had appeared upon the skin. Fortunately, outbreaks of this extreme severity were rare. Sometimes the glandular complications constituted the prominent characteristic of the attack. So, as he looked back over the past forty years, the epidemics which he had met with were found to be all different in character.

Dr. Van Gieson then spoke of the method of preventing the spread of the disease which he was accustomed to use. By way of preface, he said that scarlet fever was not contagious in the beginning. The contagious period began with the appearance of desquamation. For many years it had been his practice to use inunction to prevent the dissemination of the epithelial scales, and for this purpose he ordinarily employed an ointment with I per cent. (sometimes 2 or 3 per cent.) of sulphur, and 1/5 per cent. of menthol, to each ounce of which was added 20 minims of oil of eucalyptus. rubbed over the body twice a day until all the desquamation had disappeared. Since he had adopted this plan he had noted less spread of the disease than formerly. The inunction was also very comforting to the patient, as Dr. Kerley had remarked. The latter was right, he thought, in stating that occasionally a second desquamation occurred. He would like to ask whether any recrudescence had been observed between the two desquamations in these cases. Personally, he did not believe that there could be a second desquamation unless after the first there was a secondary attack of the disease, and he had never seen a second desquamation except in cases where this had occurred. He could not agree with Dr. Kerley in his opinion of milk in children's febrile diseases. In his (Dr. Van Gieson's) opinion it was one of the most useful articles of diet in these cases. Of late, however, he had been giving unfermented grape juice to a considerable extent, and he had found it almost as valuable as milk. For the throat conditions he was accustomed to employ hydrogen peroxide and potassium permanganate. When the disease was very severe and there was much glandular complication, he had used antistreptococcic serum to a limited extent, and it had seemed to him that the patients had been benefited by it,

Dr. H. W. BERG said that four or five years ago, when Moser first put forth his antistreptococcus serum for scarlet fever, it had been employed in twenty cases at the Willard Parker Hospital, while at the same time twenty check cases were treated along the ordinary lines. No benefit, however, was observed from this manners. In Moser's serum

the streptococcus was taken from the blood of patients that had died of virulent scarlatina. Now, if one injected the antistreptococcic serum without the proper amount of complement, very little effect would be produced, as there was a direct arithmetical ratio between the two. Such a bacteriolytic serum violated the first logical essential for the production of an antiserum. The bacterial cause of scarlet fever was unknown, and while many of the complications were due to mixed infections with the pus organisms, the death rate in this disease was certainly not due wholly to the mixed infections. It was begging the question to inject a serum for the prevention of complications and leave the primary disease untreated. An important point in scarlet fever was the relation between the fever and the eruption. The toxicity governed the amount of pyrexia, and as a rule in this disease the temperature became resolved very gradually, and not by crisis, as in measles. If, therefore, the antistreptococcic serum was a true antiserum, under its use there should be observed an immediate drop in the temperature, or, at all events, a tendency to decline. Such was not the case, however, for under this treatment the fever resolved itself by lysis, not crisis, just as when it was not employed. If he had seen a recovery in every one of the twenty cases at the Willard Parker Hospital, and yet the temperature had remained unaffected at the end of twenty-four or forty-eight hours after the first injection, he would still have been of the opinion that the serum had not caused the cure. This was the reason why he was unwilling to use antistreptococcic serum in scarlet fever.

In reply to an inquiry as to the use of diphtheria antitoxine in scarlet fever Dr. Berg said that for some time past it had been the practice to administer an immunizing dose (500 or 1,000 units) of this antitoxine to all scarlet fever patients on their entrance into the Willard Parker Hospital. This was done simply as a matter of precaution. Unless diphtheria actually occurred as a complication, he did not believe it at all advisable to give large doses of antitoxine. The antitoxine not infrequently produced quite marked cutaneous eruptions, and it was not justifiable to add another complication when the skin was already overburdened, since this extra work imposed might prove too much for the already enfeebled powers of the patient.

Dr. Kerley, in reply to Dr. Van Gieson's question, said that he had not observed a recrudescence in the cases in which a second desquamation occurred. If a secondary attack of the disease took place, it must have been so slight as to escape observation. During the last few days, however, he had seen in consultation a remarkable case of typically marked scarlet fever in a patient who had had a previous attack of the same disease only in December last. There was an interval of but six or seven weeks between the two attacks. He had not personally seen the first of these, but, it was well authenticated, as it was observed by a practitioner of experience and recognized ability, and the Health Department had accepted the case as one of scarlet fever.

Dr. J. H. R. BARRA said it had occurred to him that a preliminary funnigation of the sick room

might be of service in preventing the spread of the disease. Such fumigation might be practised during the attack, the patient being temporarily removed and then returned to the room to remain until desquamation had ceased, when the final fumigation would be carried out as at present. In the complicated cases of scarlet fever there was apt to be present a mixed infection, with both the streptococcus and the staphylococcus. Such infection would not respond to diphtheria antitoxine, but if the Klebs-Löffler bacillus was found, the indication for its use was absolute.

In reply to a question as to the percentage of cases of diphtheria occurring in connection with scarlet fever, Dr. Berg said that at the Willard Parker Hospital, for the last four or five years, during which the plan of giving immunizing doses of antitoxine to all the patients on their entrance had been carried out, the percentage of diphtheria had been very much smaller than formerly. In his private practice diphtheria occurred in about ten per

cent. of the cases.

Dr. Kerley thought that in his practice it was observed in only about five per cent, of the cases.

The Diagnosis of Meningococcus Cerebrospinal' Meningitis from Other Types of Cerebrospinal Meningitis.—Dr. Henry W. Berg read this paper. In a general way, he said, the symptoms of cerebrospinal meningitis could be grouped under two classes, namely, those due to the affection of the cerebrospinal meninges and the brain, spinal cord, and nerve trunks, and, second, those due to the toxæmia and sepsis. It followed, therefore, that this disease must be distinguished, on the one hand, from other organic diseases of the cerebrospinal system, and, on the other, from toxic and septic conditions and diseases, particularly those of a febrile character. As to the latter, both meningococcus and other types of cerebrospinal meningitis had frequently to be distinguished from cases of infectious diseases ushered in by or exhibiting during their course cerebral and spinal symptoms due to toxæmia of the nerve centres, and not to meningitis. A second class of cases was that in which the patient suffering from an infectious disease had as a complication a real organic cerebrospinal meningitis, due either to the organism causing the primary infectious disease present or to a mixed infection with some other meningitis producing organism. Thirdly, it was important from a diagnostic, prognostic, and therapeutic point of view to distinguish from each other cases of organic cerebrospinal meningitis of varying bacterial pathogenesis. Finally, it was necessary to remember that the various organic diseases of the spinal cord and brain were frequently complicated by a partial or general cerebrospinal meningitis which might simulate epidemic cerebrospinal meningitis. It was obvious, then, that the diagnosis of meningococcus cerebrospinal meningitis resolved itself into the distinction of this disease (1) from pseudomeningeal symptom complex, and (2) from other types of cerebrospinal meningitis, whether of bacterial origin or occurring as complications of organic cerebrospinal lesions.

The essential symptoms necessary for a recognition of cerebrospinal meningitis in contradistinc-

tion to toxic pseudomeningitis were numerous, and a large proportion of them would be revealed by a careful examination in almost every case, whether acute or subacute, sporadic or epidemic. In enumerating these, he said that, of the symptoms due to the involvement of the spinal cord, the Kernig sign had in the cases he had seen proved the most useful and distinctive. It was obtained by placing the patient upon the back, flexing the thigh at right angles with the abdomen, and then extending the leg upon the thigh thus flexed. If Kernig's sign was to show itself, complete extension of the leg upon the thigh could not be accomplished. The patient, even when semicomatose, complained, and cried out long before the leg was brought into a line with the thigh, and the spasmodic resistance could not be overcome even by forcible effort. As the Kernig sign diminished, the prognosis improved. While this symptom was not limited to epidemic cerebrospinal meningitis, but was present in other forms of meningitis, Dr. Berg had never found it absent in any of the cases of this disease he had seen in the recent epidemic. A large number of the symptoms described were not observed until the later stages of the disease, while many of the earlier symptoms were duplicated in toxic pseudomeningeal conditions; but, fortunately, the bacteriological diagnosis of the disease was absolutely distinctive. For the purpose of bacterial diagnosis during life, the meningococcus must be sought for in the cerebrospinal fluid obtained by lumbar puncture. It could be demonstrated microscopically and by culture, and cultures made from fluid obtained early in the disease would give positive results in a very large proportion of cases. The characteristic diplococci were most apt to be found in fluid obtained during the acute stage or during an exacerbation. In a general way, the microscopic appearance of the fluid obtained by lumbar puncture yielded some indications as to the bacteriological character of the meningeal process. Thus a purulent, turbid fluid spoke for meningococcus meningitis, a clear one for a toxic pseudomeningitis, while a comparatively limpid fluid containing flocculi or fibrinous shreds or a slender white column in the centre of the tube, branching out at the top and bottom in a test tube half filled with the fluid, indicated tuberculous meningitis. Any diagnosis resting upon such gross appearances, however, was unreliable, and should be made certain by finding the bacteria by staining or culture. In conclusion, he stated that in almost all cases of cerebrospinal meningitis, as distinguished from toxic pseudomeningitis, the normal tension of the fluid in the subarachnoid space was increased, and the fluid issued through the trocar under increased pressure.

After reading his paper Dr. Berg spoke for a few moments on the recent Flexuer serum. This, he said, was injected directly into the spinal canal, where it came into contact with the cerebrospinal fluid. The ordinary dose was 25 e.c. which was administered after about 30 c.c. of this fluid had been withdrawn by lumbar puncture. His own experience with the serum was limited to a single case, that of an adult in his service at the Mount Sinai Hospital, but the result had been brilliantly success-

ful. After the third injection the cerebrospinal fluid, which in the beginning had been purulent, was found to be perfectly clear and absolutely sterile. Recovery rapidly followed; and the same good results had been obtained in other cases at the Mount Sinai Hospital. Here, he believed, was a true antiserum, because it produced immediate effects which could not be obtained in any other way, and Dr. Flexner was willing to furnish it to all who would give him the bacterial findings and accurate clinical data of cases of the disease.

Dr. Kerley said he was glad that Dr. Berg had emphasized so strongly the necessity of employing lumbar puncture for making the diagnosis. He had seen some cases which were so mild that the diagnosis could not have been cleared up without this, and others which a few years ago would have been diagnosticated as tuberculous meningitis. There was no doubt in his mind that the Flexner serum had "made good." In a case occurring in an infant, fourteen or fifteen months old, in which the fever had been very high for ten days the temperature fell to normal after the first injection, and remained down. In five days the cerebrospinal fluid was perfectly clear, and the patient made a perfect recovery.

In reply to an inquiry by Dr. W. G. Frey as to the therapeutic value of simple lumbar puncture, Dr. Berg said that in many of his cases in the recent epidemic he had used scarcely any other treatment, with the exception of the application of ice bags. The good effect it produced he believed was due to the relief of pressure which it afforded. In this procedure sufficient fluid should be removed to relieve the pressure, and in one obstinate case, which finally ended in recovery, it had had to be repeated no less than twenty-two times. From five to cight was the average number of repetitions in his cases. He regarded it as a remedial agent of great value.

Caution Required in Accepting X Ray Evidence.—Dr. A. ERNEST GALLANT reported the case of a lady who after a fall had a swelling on the upper part of the thigh which he believed to be probably a sarcoma of the femur. As it might possibly be due to a gumma, however, he placed the patient on antisyphilitic treatment, with a negative result. He then asked an x ray expert whether he could diagnosticate a sarcoma of the femur if this was present, and, receiving an affirmative reply, he had an x ray picture taken. In sending the plate (which was presented for inspection) to Dr. Gallant, the radiographist accompanied it with a note explaining that he had found the case to be one of fracture. Although the appearances exhibited did not seem to him very convincing, Dr. Gallant accepted this diagnosis and treated the limb accordingly. As the enlargement continued to increase, however, he obtained the patient's consent to get some material from the growth for examination, and, this having been pronounced by a pathologist to be sarcoma, he amputated the limb at the hip joint. The wound healed well, and there was no further trouble until some months afterward, about the patient complained of difficulty in urination. As welling was detected in the abdomen, and e an mation shower this to be due to a parovarian

cyst. The abdomen was opened, and the growth, which was located on the broad ligament, removed. It proved to be sarcomatous also.

Betters to the Editors.

PALMAR PROJECTION OF THE ULNA AFTER COLLES'S FRACTURE.

II JONES STREET, EAST, SAVANNAH, GA., August 12, 1908.

To the Editors:

In the issue of your journal for June 13th you have an editorial entitled Palmar Projection of the Ulna after Colles's Fracture, in which you call attention to a paper by Dr. Franklin C. Clark, of Providence, who has described two cases of this deformity and who writes of it as a rare sequel of this fracture, having seen but two cases in thirty years. This statement is very surprising to me, for this deformity has long been recognized as common in bad cases of this fracture, and the literature on the subject, and a very rich literature, too, fully describes the deformity and its very evident cause, the ruptured ligaments of the wrist joint, and principally the internal lateral ligament.

It was recognized and fully described long before the use of the x ray. Nélaton recognized its chief cause in the fracture of the styloid process of the ulna with the rupture of the internal lateral ligament. And since we have had the x ray the frequent break of the styloid process of the ulna in Colles's fracture has been noted by all workers in this field. I have myself fully described it in two papers in the *Medical Record:* Some Observations on Colles's Fracture by the Aid of the X Ray, for May 8, 1897, and A Case of Colles's Fracture Treated Prone on a Flat Splint, with Chief Regard to Ruptured Ligaments; for January 15, 1898.

I have seen many cases of this deformity more or less pronounced. It is the ruptured ligaments which make so difficult often the satisfactory treatment of this fracture. The reduction and good apposition of the broken radius is a comparatively simple thing, but we have less control over the ruptured ligaments.

I quote from my first paper: "By the rupture of the internal lateral ligament and the anterior and posterior radioulnar ligaments, and a displacement of the triangular fibrocartilage, the ulna slips toward the palmar surface of the wrist—probably under the influence of the strong anterior carpal ligamentsand under the same influence slips toward the radius, showing in the radiograph an overlapping of the two bones. . . . It seems also quite evident, as pointed out by Hamilton, that the slipping of the hand toward the radial side, producing the most prominent and unsightly deformity in Colles's fracture, is due to the stretching or rupture of the internal lateral ligament principally, aided by the rupture of the anterior and posterior radioulnar ligaments, and perhaps other ligaments in addition, in conjunction with the much stronger muscular pull on the radial side of the hand."

The chief points in the successful treatment of a

Colles's fracture are, first, to overcome the deformities caused by ruptured ligaments, and, second, to promptly control the inflammation and fibrous proliferation consequent upon the severe sprain and contusion of the wrist joint.

EUGENE R. CORSON.

** Our correspondent seems to have in mind displacements of the ulna observable at the outset, whereas Dr. Clark, as we interpreted his article, had reference to ulnar displacement coming on at a late period—as a sequela, not as a concomitant feature of the injury.

161 Benefit Street.

 $To\ the\ Editors;$ Providence, R. I., August 20, 1908.

Your very kind editorial comments on my article concerning some unusual results of Colles's fracture, which I communicated to the magazine edited by my old classmate, Dr. Hersey, I greatly appreciate, and feel that my labor has met with a reception that I did not expect to find. Your comments are perfectly just, and I cannot do otherwise than accept them. The malposition does not exist primarily unless there is an apparent dislocation, or a fracture of the styloid process, of the ulna. Whether this bone is dislocated or not, the result may be the same, although at first the dislocation was properly reduced. This was an error into which Dr. E. M. Moore fell. as he thought that all fractures of the lower end of the radius were accompanied by the dislocation, to a greater or less extent, of the companion ulna. That is not the generally accepted opinion. The point that I have endeavored to prove conforms exactly with your view of the case. I did not intend to overlook any important material in illustration of my subject or to steal anybody's "thunder." But I fail to see that Dr. Corson has demonstrated in his letter that the subject is widely known. It was never taught in the textbooks adopted by the various medical schools; they are all silent on this sequela of Colles's fracture, not an immediate occurrence. As to his treatment of this fracture with the prone splint, I am very happy to find any one else falling upon my way of thinking. It was only my wish to

pare my own views with those of others. I thank you kindly for forwarding me Dr. Corson's letter for examination previous to its publication. I think you have answered it sufficiently. think that the reputation of the New York Medical Journal is a satisfactory guaranty for a favorable reception of my article among the medical profession. I shall let it stand or fall on its own merits. I wrote it frankly, and as frankly gave it to the world. If there is any adverse criticism advanced in its regard (and thus far I have had none), let it come. If my effort does not have a positive, it may obtain a negative or posthumous fame. It is all the same to me. If I should be the means of drawing from his obscurity any one who will benefit the surgical world through any good intentions of mine, it is enough. I ask no more. My object has been ac-

bring up the subject more particularly and to com-

complished.

FRANKLIN C. CLARK.

P. S.—Since writing the foregoing I have carefully read Dr Corson's two articles, the first of

which I do not find so clearly expressed as could be desired. But truth compels me to say that he specifies the true cause of the deformity at whatsoever period occurring. He is one of the few who have drawn particular attention to the subject. But the cases which I cited were two extreme cases—one due to a very great injury, including a dislocation of the ulna; the other constituting one of the simplest and slightest cases I ever had. F. C. C.

Book Antices.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Linné's Dietetik. Pa Grundvalen af dels hans eget Originalutkast till Föreläsningar: Lachesis Naturalis Quæ Tradit Dietam Naturalem. Och dels Lärjungeanteckningar efter dess hans Föreläsningar: Collegium Diteteticum. Pa Uppdrag af Medicinska Fakulteten i Uppsala. Ordnad och utgifven af A. O. Lindfors. Upsala; Akademiska Bokhandeln (C. J. Lundström), 1907. Pp. 248.

The life of Linnæus as a botanist is well known. In every elementary historical sketch we encounter the story of how as a boy of five he followed his father about in his garden, repeating the botanical names of the plants, to be severely reprimanded if he asked twice for a forgotten name; but of Linæus as a physician we know little. In this country at least Heptoen alone has called to our minds the facts that he was a physician and an able one, and that he left works on medical subjects that were striking alike for their originality and profoundness.

As a result of the recent Linnæus Fest, the Upsala Faculty have issued a number of interesting works bearing on the many sided activities of one of their most brilliant predecessors.

In the Prolegomena of Vol. IV the author deals with health, life, death, youth, diet, nature, and the

structure of the human body.

The major part of the work discusses dietetics in a very modern manner, but one too detailed to be taken up here. To any one sufficiently familiar with Swedish the work will prove of much interest, historic as well as technical.

Insomnia and Nerve Strain. By Henry S. Upson, M. D., Professor of Diseases of the Nervous System in the Western Reserve University, etc. With Skiagraphic Illustrations. New York and London: G. P. Putnam's Sons, 1908. Pp. xiii-144. (Price, \$1.50.)

To damn this book with faint praise might be the easiest way to escape an unpleasant duty, but, inasmuch as the author holds a thesis, it seems advisable to see what manner of proof is forthcoming.

The author first shows a deplorable ignorance of what is meant by the psychoses and what is being done for the treatment of the insane. He assumes that patients with "mania and melancholia and dementia præcox," when once the diagnosis is made, are shut up in asylums and then nothing is done for them.

This may be the practice in certain communities, but the reviewer doubts it. Certainly no one who has any acquaintance with the State hospitals of New York, Massachusetts, or any other of our large

commonwealths, or one who has ever been within the psychiatric clinics of Munich, Berlin, Strassburg, Florence, etc., will feel like making such statements.

Dr. Upson supports the remarkable hypothesis that the ills to which the nervous system is prone are due to disorders of the teeth. He cites a case of presumably an infectious mental affection cured by extracting a tooth. The literature of psychiatry is full of cases in which relief from a suppurative focus has brought about the recovery of an infectious disorder of the mind. Yet, fortunately, we have had no books trying to prove that mental disease is due to pyosalpinx, pyonephrosis, appendicular inflammation, hepatic abscess, etc. Our knowledge of the infectious mental diseases began with Hipprocates, and the idea that maniacal states may be due to an infectious disease is thousands of years

The author then tries to explain, on the basis of Head's researches, how dental disorders, viewed as irritative disorders of the sensory system, may affect the remainder of the nerve mechanism generally. It is to be regretted that he misquotes Head in his superficial presentation and does not prove anything. The book impresses us as a medley of many words, few thoughts, and still fewer facts.

Diseases of the Nervous System. By H. Campbell Thomson, M. D. (Lond.), F. R. C. P., Physician to Out Patients at the Middlesex Hospital and Medical School. etc. With Eight Colored and Twelve Black and White Plates, and One Hundred and One Figures in the Text. Chicago: W. T. Keener & Co., 1908. Pp. xv-480.

To be able to prepare a short, accurate, and yet satisfactory manual of the diseases of the nervous system is no mean accomplishment, yet in the small book here in question this task has been well performed.

The book is conceived in a thoroughly modern spirit, is built up on the teachings of modern nerve anatomy and physiology, is well illustrated, and altogether is commendable. It is infinitely superior to a number of small manuals on the same subject which enjoy a certain amount of popularity in this

Medicinisches Literatur ingod Schriftsteller Lademeeum, 1997-1998. Herausgeber: H. S. Meert, Bibliograph Hamburg: Francke & Scheibe, 1998. Ph. 25, 648.
Mr. Albert — bibliographer he called himself has

undertaken to publish a Who's Who et in Medicine. This is not an easy task, and the autile for has absolutely failed to accomplish it. The foreface is written in three languages, German, Engolish, and written in three languages, German, Josephish, and French; and the text contains a great deal chair English, and such English! The reformers of our English spelling should make Mr. Albert and his prefiner of their society. honorary members of their society.

The book is divided into five parts. Part I comtains the list of medical writers, with short bios raphies and lists of their publications. The author says he has corresponded with the whole medicar world and received answers to his inquiries in fourteen languages; but we hardly think that there has ever appeared such an incomplete list, and we must admire the author's audacity in offering such book; he certainly shows no great knowledge of medical writers and their publications

Part II is intended to be an abbreviated medical Minerva, with a list of medical societies of America. Part III is an apology for a list of medical journals; and Part IV is a reprint of names of medical book publishers who have answered the author's circular letter. An alphabetical index is to be found in Part V.

Collectors of curiosities we would advise to purchase the book, but not a physician or medical writer. We never have seen a book which so little fulfilled what its title page promised.

The Development of Ophthalmology in America. 1800 to ne Development of Ophthalmology in America. 1800 to 1870. A Contribution to Ophthalmological History and Biography. An Address Delivered in Abstract before the Section in Ophthalmology of the American Medical As-sociation, June 4, 1907. Revised and Enlarged. Illus-trated by Selected Portraits and Cuts. By ALVIN A. Hubbell, M. D., Ph. D., Professor of Clinical Ophthal-mology in the University of Buffalo, etc. Chicago: W. T. Keener & Co., 1908. Pp. 197. (Price, \$1.75.)

The history of medicine or of any one of its branches is interesting, and it is a great pleasure to read such a work as this which Dr. Hubbell has given us. It is not pretentious, it is rather an essay, and agrees with the following description given by the author in his preface: "It simply sketches the principal factors of its development—the men who have been most conspicuous in connection with it, and the institutions, in their beginnings, which have become perpetual fountains of ophthalmic knowledge and experience, as well as harbingers of relief to the suffering and the blind." To go a little more into detail, the scope of the work is shown by the headings of the chapters into which it is divided, the factors of development, biographical sketches of Dr. George Frick, the father of American ophthalmology, and of other early surgeons. American ophthalmological literature to 1850, special American contributions, the transition period from the ophthalmology of the physician and surgeon to the ophthalmology of the specialist, the pioneer specialists, the rapid changes after 1850. other factors of advancement, and the new American ophthalmology. We certainly hope that the author will be so gratified by the reception accorded to this work that he will do as he intimates, and soon furnish us with another volume comprising the American ophthalmology from 1870 down to the present time.

Public Health and Marine Hospital Service:

Official list of changes of stations and duties of com-missioned and other officers of the United States Public Health and Marine Hospital Service for the seven days ending August 19, 1908:

Delgado, J. M., Acting Assistant Surgeon. Granted leave of absence for three days, from August 4, 1908, on ac-

of absence for three days, from August 4, 1908. on account of sickness.

FAUNTLEROY, C. M., Assistant Surgeon. Directed to proceed to the Marine Hospital at Mobile, Ala., for special temporary duty, upon completion of which to rejoin his station at New Orleans, La.

HOLT, J. M., Passed Assistant Surgeon. Granted leave of absence for sixteen days, from August 15, 1908.

KALLOCH, P. C., Surgeon. Directed to proceed to the Marine Hospital, Portland, Me., for special temporary duty, upon completion of which to rejoin his station at Portland. Me., Ouarantine Station.

Portland, Me., Quarantine Station.

Keiller, William, Acting Assistant Surgeon. Granted leave of absence for seven days, from August 7, 1908: granted leave of absence for twenty-three days, from August 13, 1908.

MAGRUDER, G. M., Surgeon. Granted leave of absence for seven days, from August 2, 1008, under paragraph 101. Service Regulations

Mason, W. C., Acting Assistant Surgeon. Granted leave of absence for seven days, from September 13, 1908.

OAKLEY, J. H., Passed Assistant Surgeon. Directed to assume temporary charge of the Marine Hospital at Port Townsend, Wash., during the absence of Surgeon W

G. Stimpson.

REIMER, H. B. C., Acting Assistant Surgeon. Granted leave of absence for six days, from August 10, 1908.

RICHARDSON, S. W., Pharmacist. Detailed to represent the service at the meeting of the American Pharmaceutical Association, to be held at Hot Springs, Ark., September 7 to 12, 1908, upon completion of which to rejoin his station at Buffalo, N. Y.

ROEIRIG, A. M., Pharmacist. Detailed to represent the service at the meeting of the American Pharmaceutical

service at the meeting of the American Pharmaceutical Association, to be held at Hot Springs, Ark., September 7 to 12, 1908, and directed to stop at the Bureau en route to Hot Springs; upon completion of which to

rejoin his station at Stapleton, N. Y.
Schereschewsky, J. W., Passed Assistant Surgeon.
Granted leave of absence for one month, from August

17, 1908.

SINCLAIR, A. N., Acting Assistant Surgeon. Granted leave of absence for twenty-five days, from August 12, 1908. STIMPSON, W. G., Surgeon. Directed to proceed to Tatoosh Island, Wash., for special temporary duty, upon completion of which to rejoin his station at Port Town-

pletion of which to rejoin his station at Fort Fownsend, Wash.

Vocel, C. W., Passed Assistant Surgeon. Directed to report to the Director of the Hygienic Laboratory, Washington, D. C., for temporary duty.

WATSON, HARVEY J., Acting Assistant Surgeon. Granted leave of absence for thirty days, from September I,

WILSON, A. G., Acting Assistant Surgeon. Granted leave of absence for seven days, from August 13, 1908.

Boards of medical officers were convened to meet on August 24, 1908, for the purpose of making a physical examination of applicants for the position of cadet in the Revenue Cutter Service, as follows:

Baltimore, Md.: Passed Assistant Surgeon J. T. Burkhalter, chairman; Acting Assistant Surgeon C. Hughes, recorder.

Hughes, recorder.

Boston, Mass.: Surgeon R. M. Woodward, chairman; Assistant Surgeon T. W. Salmon, recorder.

Chicago, Ill.: Surgeon C. B. Young, chairman; Assistant Surgeon C. E. Wood, recorder.

Detroit, Mich.: Surgeon Fairfax Irwin, chairman; Passed Assistant Surgeon M. J. White, recorder.

Galveston, Tex.: Passed Assistant Surgeon G. M. Corput, chairman; Acting Assistant Surgeon W. H. Gammon, recorder.

recorder.

Mobile, Ala.: Acting Assistant Surgeon J. O. Rush, chairman; Acting Assistant Surgeon C. S. Cater, recorder.

Xew York, N. Y.: Passed Assistant Surgeon J. A. Nydegger, chairman; Passed Assistant Surgeon C. H. Lavinder, recorder.

etr, recorder.

Philadelphia, Pa.: Surgeon J. M. Gassaway, chairman;
Acting Assistant Surgeon H. Horning, recorder.

Portland, Me.: Surgeon P. C. Kalloch, chairman; Acting
Assistant Surgeon A. F. Stuart, recorder.

San Francisco, Cal.: Surgeon H. W. Austin, chairman;

San Francisco, Cal.: Surgeon H. W. Austin, chairman; Passed Assitant Surgeon W. W. King, recorder, Seattle, Wash.: Passed Assistant Surgeon M. W. Glover, chairman; Assistant Surgeon C. W. Chapin, recorder, Washington, D. C.: Assistant Surgeon General J. M. Eager, chairman; Assistant Surgeon General J. W. Kerr, recorder.

Army Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Army for the recek ending August 22, 1708

BARNEY, FRED M., First Lieutenant. Granted thirty days' leave of absence.

BRUNS, EARL H., First Lieutenant. Upon the expiration of present leave of absence will proceed to Fort Monroe,

Va., for station and duty.
CULLER, R. M., Captain. Relieved from duty at Fort Monroe, Va., and ordered to Fort Logan H. Roots, Ark., for tation and duty

LE WALD, LEON T., Captain. Granted twenty-five days' leave of absence

REASONER, M. A. First Lieutenant. Granted leave of absence for twenty-four days.

SHORTLIDGE, E. D., Captain. Granted fifteen days' leave of absence.

SNYDER, H. McC., First Lieutenant. Relieved from temporary duty at Fort Rosecrans, Cal., and ordered to return to San Francisco, Cal., and resume duty at the

Army General Hospital.

TEFFT, WILLIAM H., Captain. Having completed the duty for which he was ordered to Washington, D. C., will

return to station in Cuba.

TORNEY, GEORGE H., Colonel. Ordered to proceed at once from San Francisco, Cal., to Alascadero Ranch, Cal.. for duty in connection with laying out camp and sanitation of same.

WILSON, ELSWORTH, First Lieutenant. Relieved from duty at the Department Rifle Range, Cal., on completion of target practice, and ordered to Fort Rosecrans. Cal.,

for temporary duty.

WOODRUFF, CHARLES E., Major. Granted three months' leave of absence, to take effect on or about September 8, 1908.

The following first lieutenants were ordered to active duty in the Medical Reserve Corps service of the United States: Frank M. Wells, Daniel P. Card, M. H. Bowman, G. E. Chamberlain.

Navy Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Navy for the week ending August 22, 1908:

BISHOP, L. W. Passed Assistant Surgeon. Ordered to temporary duty at the Navy Recruiting Station, New York, N. Y. York, N.

DIEHL, O., Surgeon. Detached from the Navy Yard, Philadelphia, and ordered to the Charleston and to additional duty as fleet surgeon of the third squadron, Pacific Fleet.

Surgeon. M. F., GATES. Detached from the Charleston

and ordered to the Navy Yard, Philadelphia, Pa.
LANDO, M. E., Assistant Surgeon. Detached from the
Navy Recruiting Station, Minneapolis, Minn., and ordered to Washington, D. C., September 14, for examination for promotion, and then to await orders.

McDonnell, W. N., Passed Assistant Surgeon, Detached

from duty in connection with the Navy Rifle Team, Camp Perry, Ohio, and ordered to the Navy Recruiting Station, Minneapolis, Minn.

Births, Marriages, and Deaths.

Corruster.— In Plainfield, New Jersey, on Monday. August 10th, to Dr. Harold D. Corbusier and Mrs. Corbusier, a daughter.

Married.

BINGHAM-HEIZMANN.-In Buffalo, on Tuesday, August 18th, Dr. Ernest G. Bingham, United States Army, and Mis Laura Churchill Thompson Heizmann.

Cushing.—In Brookline, Massachusetts, on Friday. August 14th, Dr. Ira B. Cushing, aged sixty-two years.
Dunn.—In Oakland, California, on Thursday, August
13th, Dr. James P. H. Dunn, aged forty-five years.

Duvalt.—In Louisville, on Wednesday, August 12th, Dr. Henry Arthur Duvall, aged sixty-one years.
NICKERSON.—In Fort Collins, Colorado, on Wednesday, August 19th, Assistant Surgeon Dr. William N. Nickerson,

August 19th, Assistant Jungeon Dr. Whitain M. McKelson, United States Navy, retired.
PARISH.—In Maryland, New York, on Saturday, August 15th, Dr. Charles E. Parish, aged fifty-three years.
SMITH.—In Brooklyn, on Thursday, August 20th, Dr.

George H. Smith, aged sixty-four years.

SMITH.—In Durham, North Carolina, on Saturday,
August 15th, Dr. Julien A. Smith, aged fifty-three years. Wood In Boston, Massachusetts, on Friday, August 14th, Dr. Stephen V Wood

CANCER OF THE RECTUM.

A Study of One Hundred Consecutive Operations for Malignant Growth of the Rectum and Sigmoid.*

By JAMES P. TUTTLE, M. D., New York.

The large percentage which cancer of the rectum and sigmoid bears to cancer of the human body as a whole makes it a subject of deep interest to all physicians. The fact that, notwithstanding what has been done for these growths in other parts of the body by radium, x rays, Finsen lights, escharotic medicines, etc., nothing has ever cured a patient of cancer of the rectum or sigmoid except operative interference, makes these conditions peculiarly in-

teresting to the surgeon.

I shall not go into the literature, or bring before you a long chapter of statistics on the subject of cancer. You know too well its ravages, its rapid increase, and the futility of our attempts to eradicate it. We do not know its cause, and have no means to prevent it. Our last resort, for the present, is to cure it if possible, when it has once appeared. What are we accomplishing in this respect? Do the results of our present methods justify their continuance? Ought cancer of the rectum and sigmoid to be extirpated? If so, when and how? These are questions which occur to every one who operates in this line.

The experience of equally prominent surgeons differs so greatly that one cannot answer for the other. Experience, technique, good fortune in his cases-call it luck if you will, and environments, give one man a success which his more talented brother perhaps cannot approach. Each must. therefore, be guided by the results of his own work, as to whether he should continue, and if so whether he should pursue his present methods or adopt others. One may, however, be lulled into satisfaction with his own work by a few successful cases, the gratitude of patients, or the flattery of friends when the work does not justify it. It is well, therefore, for us to present, from time to time, our records to the public for critical analysis. I take this opportunity to bring before this body of American surgeons the histories and results of one hundred cases operated on for cancer of the rectum and sigmoid. The period comprised is June, 1892, to February, 1908. The total number operated on is 108; but the histories of eight were lost in the Polyclinic

*Read before the Section in Surgery of the American Medica Association, in Chicago, June, 1908.

Hospital fire, in 1896, and are not included in this presentation.

A brief résumé of the results is necessary to begin with. The total immediate deaths from one hundred operations has been thirteen, a mortality of thirteen per cent. The known recurrences which we presume will end or have already ended in death are twenty-four. The number of patients known to be living and free from the disease is forty-one; this leaves twenty-four unaccounted for, patients who have disappeared in our great metropolis, or who have gone broadcast over the world, who may or may not have had recurrences. They were all free from the disease up to the time of our last observation, from three months to five years after the

What are the conditions which have influenced these results and which being altered might have made them better? Age, sex, the period of the disease when the operation was performed, the preparation of the patient, the pathological nature of the disease, the site and extent of the tumor, the parts involved, the character and technique of the operation done, the disposition of the intestinal ends, and the after care of the patient.

What are the conditions which justify or condemn our procedures? The immediate mortality, the frequency and date of recurrence, and last, but most important of all, the health and comfort of the patient after operation. Let us study these in detail as exemplified in the cases presented.

CONDITIONS INFLUENCING RESULTS.

Age.—Old people in good health, as a rule, bear aseptic operations well. This is not true in long operations, where there are likely to follow kidney or liver affections; in bloody operations, because they do not remake blood as quickly as the young; and in operations followed by free and prolonged suppuration in which vital resistance and good recuperative powers are necessary to withstand the drain. The operations for cancer of the rectum and sigmoid comprise all of these contraindications, hence the high mortality among those over sixty years of age (twenty-eight per cent.). On the other hand, cancer removed from elderly people is not likely to return; in the fifteen patients above sixty years there are only two recurrences. chances of permanent cures are therefore better if the operation is survived. This is not borne out altogether by the table, for of the eight patients under thirty years who were operated upon there is not a single known recurrence. This must not be accepted too literally, however, for of these cases

five patients disappeared before the usual period of recurrence had arrived, they having been observed twenty-four, twelve, eighteen, twenty, and seven-

teen months respectively.

What appears to be established is the fact that thirty to forty years of age is the most unfavorable period for operation so far as mortality or recurrence is concerned. In this decade we find nineteen cases, with two deaths, eight recurrences, and five patients disappeared before two years had elapsed.

Total cases Deaths: Recurrences: Age period Age period 21 to 30 years 31 to 40 years 41 to 50 years 51 to 60 years 61 to 70 years 71 to 80 years

Our conclusions from these tables are that while the very old are more liable to die from the operation than the young people, the chance of perma-

nent recovery is better among them.

Sex.—The influence of sex upon cancer of the rectum is well known; the preponderance being in favor of males, and it is borne out by the present list of cases. There were sixty-four males and thirty-six females. No satisfactory explanation of this fact has ever been given, for the conditions which are supposed to produce cancer, such as produce traumatism of the bowels, are much more frequent in women than in men. The mortality in operations on the two sexes is not far apart, being 12.5 per cent. in men and 13.9 per cent. in women. The only distinction which can be made is that which has been observed—i. e., women bear the combined operation much better than men.

Period of existence of the tumor before operation.—The influence of this upon the results of operation, both immediate and remote, is most interesting; but, unfortunately, our records, or any other so far as I can find, give no satisfactory informa-tion concerning it. The periods during which the patient had suffered from rectal symptoms, so far as they knew, are summarized in the following table, which shows very little advantage of early over late discoveries. In fact, the table shows that the second highest mortality is among those whose symptoms had lasted the shortest time. In comparing these cases, however, we find that the majority of patients who have come under early observation had had either mild epithelioma at the margin of the anus, or very malignant rapidly progressing adenocarcinoma. In the first class the patients got well very quickly; in the second class the patients either died from the operation or had early recur-

21.4 per cent 6 6 per cent 14.3 per cent.

If we leave out those very early cases which bear a peculiar malignancy, it is clear that there is a gradual increase in mortality for every month's delay in the diagnosis; but rectal symptoms are not always cancer symptoms; and most of the patients who say that they have been suffering from rectal disease for one or two years have probably had malignant transformation a few months only; the gradual change from the benign to the malignant

has been imperceptible; the patient suddenly awakes to the fact that he is worse, and his old symptoms have changed into new and different ones. It is this insidiousness of attack, this imperceptible engrafting of the malignant upon the benign disease that makes internal cancer so dangerous. It is important, therefore, that the general practitioner and family physician should be on the alert for such developments, and should know and bear in mind all the symptoms which indicate a probability of the existence of this disease.

One asks what are the first symptoms of cancer of the rectum? There are no subjective symptoms peculiar to it. Is it a question of pain; there is none in the early stages unless the margin of the anus is involved. Does one look for blood and discharge? These are both late manifestations. Constipation, which is usually referred to as one of its first symptoms, is not evident until the growth has encroached upon the calibre of the gut to such an extent as to produce stricture. On the other hand, our records prove that constipation of various degrees of intensity is exhibited in over forty per cent. of the cases seen, for a greater or less number of years, before the active symptoms of cancer appeared. The question arises, therefore, may not constipation, the irritation of arrested hard fæcal matter, be the exciting cause of malignant invasion. This gives us one clue to early diagnosis; indicating the advisability of periodical examination of the rectum in constipated patients just as we do the urine in nephritic cases.

Diarrhœa, or, more properly speaking, a desire to go to stool more often than usual without passing anything, or only passing small shaped pieces of fæcal matter or mucus; the call to stool immediately on arising in the morning; the change from diarrhœa to constipation, and vice versa; the loss of weight; flatulence and indigestion associated with stool irregularity; each demands a rigorous local examination, and such an examination is the only

means of diagnosis.

Methods of diagnosticating cases without symptoms.—The means of diagnosis employed have been the finger, the specimen forceps, the pneumatic proctoscope, and the whole hand. Whenever the tumor can be touched by the finger no instrument is necessary to determine its malignancy if the examiner is experienced. When it is too high for this it may be reached by the proctoscope and specimen forceps, a piece being taken out for microscopical examination. One must not be too reliant upon the reports of such specimens, however. Three times in this series the author has received reports that the growths were benign, when examination of the entire tumor after removal showed unquestionable malignancy. All the cases of carcinoma of the sigmoid have been diagnosticated by the pneumatic sigmoidoscope; without the pneumatic attachment this is a dangerous instrument in such cases, but with it it is perfectly safe. It should always be used without an anæsthetic, and never pushed beyond the open calibre of the bowel.

The entire hand was introduced into the rectum for diagnosis in six of these cases, where acute flexures of the bowel rendered it impossible to introduce the sigmoidoscope. I have had no accidents or bad results from this procedure. But here the large handed surgeon, one who wears over a seven and three quarter glove, must desist from this procedure; happily the diagnosis can be made

in most cases without it.

The importance of high examination of the rectum in all cases where there are symptoms possibly indicating cancer is brought out by the fact that thirteen of my patients had been operated upon for hæmorrhoids and fistula within a short time before they were brought to me with cancer. The latter had been certainly present at the previous operation

in every case.

The pathological nature of the tumor for which the operation was done.-Adenocarcinoma comprises a very large percentage of the malignant tumors of the rectum. In our series we have epithelioma, four; sarcoma, six; malignant papilloma, two; scirrhus cancer, two; colloid cancer, two; adenocarcinoma, eighty-four. Of these various types there has not been a single immediate death except in those denominated adenocarcinoma; there were three recurrences in the six cases of sarcoma, death following in each instance; while there were twenty-one recurrences and thirteen deaths in the eighty-four cases of adenocarcinoma, making a mortality of 15.4 per cent., and a recurrence of thirty per cent. As to the mortality, I cannot say that the character of the tumor had a great deal to do with it; almost all our deaths have occurred from infection, or from intercurrent causes, over which the type of the tumor could have had no influence. As to recurrences, however, it has everything to do; the nearer the tumor approaches the epithelioma, in other words, the nearer it is to the margin of the anus, the more likely and sooner it is to recur after removal.

Our pathologist has, in a number of instances, described the tumors as malignant carcinoma, and in others as mild. By malignant he means the medullary type of growth, which is distinguished clinically by its soft, friable, easily puncturing characteristics; the harder and firmer the tumor is, the less malignant it is, and the less liable to return. A careful examination of the cases will show that those in which the tumors were dense and hard have usually resulted in permanent cures; while those in which they were soft and easily penetrable have more often resulted fatally or in early recur-

rences.

Colloid.—In our early studies we were taught to consider colloid degeneration as one of the marks of intense malignancy; in the two instances in our series in which the tumors had undergone this change both of the patients have not only recovered, but have lived well beyond the average period of life after operation.

Sarcoma.—In the six cases of sarcoma, as might be expected, there were three (fifty per cent.) recurrences and metastasis; at the same time there were three patients who have made permanent and most satisfactory recoveries.

Character of neoplasm, its influence on death and

| | recurrence. | | |
|----------------|-------------|---------|--------------|
| Type | Recoveries: | Deaths: | Recurrences: |
| Epithelioma | 4 | 0 | 1) |
| Sarcoma | 6 | 0 | 3 |
| Papulloma | 2 | 0 | 0 |
| Scirrhus | 2 | 0 | O |
| Colloid | 2 | 0 | 11 |
| Adenocaremonia | 81 | 1.3 | 21 |
| | | | |

One might say it would be well to know the type of these tumors before operating, that he might give a more positive prognosis. While this would be very interesting, I am of the opinion that it would be unfortunate, because it would not influence us in the operation, and would only add to the discouragement of the patients in those cases where extreme malignancy was known in advance.

The site and extent of the tumor.—This is perhaps one of the most important topics in connection with these studies. As the following table will indicate, the percentage of death increases the higher the tumor ascends into the bowel. The percentage of recurrence is exactly the reverse. Of the eighten growths within two inches from the anal margin, there were ten recurrences, but not a single death; whereas, in the thirty-two growths above five inches there were seven deaths and only six recurrences. The explanation of this is rather clear to my own mind; it consists in the preponderance of lymphatics around the lower end of the anus, compared with those in the upper region; this experience is in keeping with that of all great surgeons who have operated along those lines.

Location of the tumor and its influence on death and recurrence.

| Site: | Recoveries: | Deaths: | Recurrences: |
|-----------------------|-----------------|---------|--------------|
| Under 1 men | | 0 | 6 |
| I to 2 inches | | 0 | 4 |
| 2 to 3 inches | | I | 2 |
| 3 to 4 inches | | I | 4 |
| 4 to 5 inches | 12 | 4 | 2 |
| 5 to 6 inches | 9 | 0 | 1 |
| 6 to 7 inches | 10 | 3 | 1 |
| Above 7 inches | I4 | 4 | 2 |
| In thirteen coops the | cita was not no | tod | |

Extent of the tumor.—So far as the extent of the tumor is concerned, the actual amount of gut involved by the growth is not so important as the amount which is to be excised in order to eradicate the glands of the mesentery which are involved, and also to obtain a healthy circulation in the proximal end. In the list presented there are two cases in which we have excised as much as sixteen and eighteen inches of the gut respectively, and yet made end to end union with excellent results. As Byron Robinson has well shown, it is not impossible to remove almost the entire sigmoid and bring the gut down almost to the anus, with perfect circulation, provided one is careful not to cut the trunk vessels in his dissection.

In the thirteen deaths which we have observed there has not been an unusual amount of the intestine removed in any instance. The one death which occurred by sloughing from improper circulation was due to the fact that the inferior mesenteric artery was torn off by too great tension during the operation, and the gut was not brought down sufficiently far to find a segment in which the circulation was maintained; this patient stood the operation well, was free from shock, and would undoubtedly have recovered had this precaution been taken. Barring the difference in shock, it is a matter of little moment whether one removes four or fourteen inches of the gut. There are no more satisfactory results in the one hundred cases than those in which I removed eighteen, sixteen, twelve, and ten inches, respectively.

The extent of the gut involved by the tumor is important only from this point of view, the larger

and more extensive the tumor the longer it has existed, and consequently the more likely will there be constitutional invasion; this latter, however, should be carefully observed and considered before a radical operation is advised; if one cannot satisfy his mind that there is not constitutional or liver invasion by a local examination, he should always do an exploratory laporotomy to clear this question before subjecting the patient to the shock of an operation that will do him no good if the liver and prævertebral glands are affected. This is one great advantage of the combined operation in high cancer, viz., that it gives one the opportunity to explore the glandular and hepatic organs before excising the growth.

Organs involved.—Leaving the sigmoid out of account there were sixteen cases in which other organs than the rectum were involved. Of these there were eight cases in which the prostate was involved in the process, either from extension of the growth or from inflammatory adhesions. Of this number two patients died from the operation, three from recurrences within a year, and three were cured. There were three cases in which the vagina was markedly involved, and one in which the uterus was also involved in the growth; of these patients one lived and two died from the operation. There were a number of cases in which the rectum was adherent to the bladder, ileum, and prostate by an inflammatory process, but these have not been taken into account.

Judging from this list, it would seem that cases in which secondary involvement of other pelvic organs has taken place furnish very unpromising results from operations, by any method whatever; that whenever the growth has existed long enough to pass from one organ to another, either by extension or metastasis, it will already have invaded the tissues to such an extent that no operation, no mat-

ter how radical, will eradicate it.

Preparation of the patient.—The proper preparation of the patient is the same whatever operation is performed. In our earlier cases we did not take so much time or care in preparation for the operation as in the later cases of the series, and we believe that the lowered mortality in the latter is more largely due to this than to improved skill in operating. Formerly, as will be seen by the histories, we operated in three or four days after the patient was first seen. More recently, however, we take a full week or more in the preparation of our patients. This preparation depends upon whether the stricture is permeable by fæcal matter, or not. If the calibre is wide chough to permit a free passage of semisolid fæcal matter, then there should never be any question as to a preliminary artificial anus. If the calibre is so contracted, however, that it would not permit of a thorough cleansing of the intestinal canal above the growth, one of two things has to be done; either the growth has to be curetted and the calibre widened, or, as in three instances only, a preliminary colostomy has to be done. I shall not describe the technique of either of these procedures, as they are familiar to all, but proceed with the ordinary preparation for operation.

First the patient is put upon a diet of eggs, milk, beef juice, rice, hominy, and white meat once a day; he is fed often in small quantities, and is given every morning before breakfast a full dose of Epsom salts, with twenty grains of sodium bicarbonate, enough to give him two or three liquid passages daily. If he is used to alcohol beverages he is given eggnog two or three times a day, and plenty of water to make up for the drastic purges. Morning and evening he is washed out with an enema of one to two quarts of a ten per cent. solution of hydrogen peroxide.

On the night before the operation the patient is placed on large doses of deodorized tincture of opium and camphor, in order to entirely control the bowels, and this is continued for eight days after the operation. The patient is always shaved as for a perineal and abdominal operation combined, for one can never tell when he may have to abandon one and adopt the other. On the morning of the operation the patient's rectum and sigmoid are washed out with a fifty per cent. solution of hydrogen peroxide, the rectal tube being left in to allow the escape of gases; just before the operation, after the patient has been anæsthetized, four to six ounces of fifteen volume peroxide is injected above the tumor if possible.

As to medications, from a bacteriological point of view, I have found nothing that thoroughly sterilizes the rectum; but from experience, the patients in which I have given full doses of beta naphthol have had less sepsis than the others. This preparatory treatment has been given in the last sixty cases, in which there have been six deaths, a mortality of ten per cent.; and it undoubtedly has had something to do with the improved results.

Character and technique of the operation done.— Next to the results obtained in this series of cases one's interest will centre, no doubt, upon the methods employed. The following table will exhibit these and the results:

| Operative methods: | | Immediate deaths: | Recurrences: | Mortality: |
|-----------------------|-----|----------------------|--------------|-------------------|
| Kraske's (including - | | | | |
| Kocher's) | | 2 | 2 | 33 per cent. |
| Bone flap | 25 | 4 | 6 | 16 per cent. |
| Perineal | 40 | 2 | 10 | s per cent. |
| Vaginal | .3 | - () | 1 | o per cent. |
| Combined operation. | . 8 | 3 | 0 | 37.5 per cent. |
| Abdominal | 9 | 1 | 4 | 11 per cent. |
| Local excision | 5 | 0 | 1 | o per cent. |
| Intrarectal resection | | f) | | o per cent. |
| Curettage and electro | | | | |
| contony | , | | | to front old to I |

As to the Kraske operation, including two of Kocher's, the six cases, with two deaths, thirty-three per cent. mortality, presents rather a discouraging aspect. The high mortality here is accidental, and does not afford a fair estimate of the method. The deaths were from avoidable causes and not attributable to the operative technique; with our present experience I do not believe either of those patients would have died.

The bone flap method, twenty-five cases, with a mortality of sixteen per cent., is more encouraging, and yet this is not what it should be in view of our present greater dexterity in operating and better technique in asepsis. It will compare favorably, however, with other statistics derived from parasacral operations; notwithstanding this it is still far

behind the results of the perineal method, in which we have forty cases with two deaths, a mortality of

five per cent.

The abdominal method comes next to the perineal, showing nine cases, with one death, a mortality of eleven per cent. These cases were all high up in the rectum or sigmoid, surrounded by few lymphatics, and involving no other organs, thus affording an opportunity for clean, aseptic resection.

The vaginal method presents a record of three cases without a death; the number is too small,

however, to prove much with regard to it.

The one case marked intrarectal resection has given an excellent result; but the patient gave me great anxiety, and I have never had the temerity to repeat it, even if I had had a favorable case.

Finally, we come to the combined operation; which, theoretically, is the ideal operation, and often the only one justified in the cases presented. Our experience has been small, but unfortunate, in its use. In all we have had eight cases, five women and three men, with a mortality of 37.5 per cent. Of the women, one died out of five, and of the men two out of three. This is discouraging; but it is a little better than the reports of some of our European confrères. Before condemning it, one must consider that the operations for which it is done are always those of great magnitude, cases which are inapproachable from below, and which cannot be removed entirely by the abdominal method.

The cause of death in every case has been infection, and it is interesting to note that while our first three patients died, our last five have all lived, showing, I hope, an improvement in our operative

measures.

The trend of my practice has been toward less and less bone cutting, and I have found that there are few, if any, cases in which the growth can be removed by the parasacral methods that it could not be done by the modern perineal method. More experience and dexterity are necessary in the latter than in the former, but when once learned it is easier, quicker, and attended by less shock and hæmorrhage than the parasacral procedures. a man with large hands this may not be the case, as the working space in the pelvis is quite small, especially in men; for this reason the operation of choice will sometimes depend upon the physical characteristics of the surgeon himself, rather than upon the patient's condition; and a tumor that can be easily removed by a man with small hands by the perineal route will have to be removed by the sacral route by one with large hands. The sooner the surgeon recognizes his limitations in this regard the better will be his results.

The technique of all these operations is more or less known. I shall describe the three, however, which appeal to me most, and in which I differ somewhat from other operators; asserting no priority in any of them, but simply a variation in

technique.

The bone flap, or Rehn-Rydigier operation.—Contrary to the method of its originators, I place the patient upon the left side, with his hips flexed upon the body, and a sandbag underneath the pelvis, thus raising the body into a semikneechest posture. The first step in this operation consists in closing the

anus with a suture, after having injected the peroxide high into the rectum. This is done to prevent the escape of intestinal contents, also to avoid the temptation to introduce the finger into the rectum during the operation, and thus cause infection. This having been done, an incision is made from a level of the third sacral foramen parallel to the border of the sacrum and coccyx, to a point one half inch back of the anus. The incision is carried quickly through all of the tissues into the cellular area back of the rectum; the hand is introduced through this incision and the rectum loosened from its attachments to the anterior surface of the sacrum; this wound and the hollow of the sacrum is then tightly packed with gauze. An incision across the posterior wall of the sacrum from the upper limits of the first is now made, and the sacrum cut through with a chisel, between the third and fourth foramina; as soon as this is done the bone flap is pulled out and dropped downward, being held in this position by a heavy forceps. The right lateral and middle sacral arteries, having been cut in this procedure, are either clamped or tied, and usually these are the only vessels that need ligation in this part of the operation. A wide access is thus furnished to the rectum and its surrounding parts. The operator at once proceeds to dissect his way around the rectum and enters the peritoneal cavity as soon as possible. This being done the lateral supports of the rectum are severed: the mesorectum is loosened from the sacrum by a clean incision of the peritoneal attachments on either side. The cellular tissue between the folds is peeled off from the bone with the fingers, and thus the main vessels, or hæmorrhoidal arteries are not wounded; the tumor can now be drawn down as far as is necessary. Having completed the intraabdominal dissection one closes the peritoneal cavity before opening the rectum, by sutures attaching it to the circumference of the gut itself. The gut is then clamped off above the tumor by two strong clamps and cut between with a Paquelin cautery; the lower end is then pulled downward and loosed from its attachments to the prostate, urethra, and surrounding tissues, the dissection being made from above downward. The purse string suture at the anus is now cut loose, and the contents of the bowel evacuated, the upper wound having been packed off before this is done; the gut is now cut off well below the tumor, and if it is within one and one half inches of the anus, the latter is everted by forceps carried through the anus from above, the proximal end is invaginated through this and sutured to the everted edge of the distal end outside of the anus; if it is above one and one half inches end to end union is employed; the upper and lower ends are brought into apposition and sutured with through and through sutures, and afterward with a row of Lembert sutures; this being done, a large drainage tube is passed up through the sutured juncture. The sacral cavity is packed loosely with gauze. The boneflap is replaced, and the bone sutured with silver wire or catgut through the peri-

If the gut comes down easily and the circulation is good it is better to adopt the Hochenegg procedure, dissecting the mucous membrane from the anal canal and invaginating the sigmoid through this opening and suturing it to the margin of the skin. In one hundred cases there were twenty-two resections with end to end sutures; there were only four instances in which there was not fæcal leakage into the wound, ulceration, and obdurate fistula; it is true that these fistulas are of no great inconvenience, and they usually heal spontaneously, but are they necessary?

The perineal operation.—The patient having been prepared, is placed in the lithotomy position, with the hips elevated above the head. After injecting peroxide into the rectum, a small circle of mucocutaneous tissue is dissected up around the anus and tied with silk ligature, thus closing the rectum entirely, so that the fæces cannot escape, and the finger cannot be introduced. The end of this circle is burnt with pure carbolic acid or the actual cautery in order to completely disinfect it. The sphincter muscles are then dissected loose, and split anteriorily as far as the perineal body and posteriorly two or three inches back of the tip of the coccyx on the right. The posterior incision having opened the retrorectal cellular space, the finger is introduced and the rectum is loosened by blunt dissection above the levator ani muscles on either side; the gut is also separated from its attachment to the sacrum in the same manner, and these spaces filled in with gauze; the finger is now introduced above the levator ani muscle, and this is cut loose from the rectum from behind forward on either side. The gut is thus practically dissected out except for its attachments to the prostate and bladder or to the vagina in front. Before the dissection is begun in this area one should introduce a full sized sound into the male urethra and bladder, so that he may be guided in his approach to these vital organs; this having been done, the rectum is dissected loose and the peritoneal cavity entered. If the tumor is above the cul-de-sac as soon as this cavity is opened one incises the lateral rectal supports back to their attachments to the sacrum, and cuts the peritoneal portion of the mesorectum on either side, by a clean incision, as high up as is necessary to bring the gut down and ablate the tumor. When the lateral folds of the mesorectum have been cut and the gut is still held above, one should avoid exercising too much traction upon it lest he should tear the blood vessels, which are its chief support. It is better to find the retracting band, clamp it with two clamps, and cut between them than to exercise force in dragging down the rectum. By careful manipulation one can ordinarily bring down from eight to ten inches, or more, of the gut, which is usually sufficient to extirpate the tumor and bring healthy gut down to the anus.

Having loosened the gut sufficiently to eradicate the tumor, one should close up the peritoneum by sutures, attaching it to the circumference of the rectum; the musculature of the rectum and anus should then be sutured by layers to the peritoneal surface of the gut, entirely closing in all dead space in the perinæum anterior to the gut. The gut is then amputated outside of the wound, its walls being cut through little by little and its mucous membrane sutured to the margin of the skin. This being completed, the sphincter is brought together anteriorly and posteriorly; if there is considerable

oozing the retrorectal space is packed with sterile gauze, through which a drainage tube is run to keep it moist. If there is not much oozing, I have found it a good plan to carry two or three silkworm sutures through the mesentery and muscular wall of the gut, as high up as possible and embracing about one third of its circumference; the loose ends are then carried out on either side of the sacrum and tied over a roll of gauze. By this means we close up the dead space posterior to the rectum, thus hastening healing and also introduce guy ropes, which hold the gut down and prevent traction on the anal sutures. A Lynch tube is introduced to allow the escape of gases and hold the parts in apposition. The dressings are held by adhesive straps, rather than by a T bandage, which so often slips and disarranges the pads.

Combined operation.—The combined operation consists in loosening the gut from its attachments within the abdomen, closing the perineal floor, and removing the growth by either the sacral or perineal method after the abdomen is closed. technique which we have recently employed is to put the patient, having been prepared and shaved, in the Trendelenburg position at once; open the abdomen and pack off the small intestines from the pelvic cavity; the sigmoid is brought out of the abdominal wound, and the inferior mesenteric artery is found and ligated as low down and near the tumor as possible. The mesorectum or mesosigmoid is then cut through on either side; the peritoneal fold between the bladder and rectum is severed in front; and the gut and rectum are loosened up by blunt dissection down to the tip of the coccyx behind and the prostate in front. If the tumor is large and one can accomplish it, it is best to cut the gut off below the growth, between the two ligatures, and take it out through the abdominal wound, as it is sometimes difficult to get a large growth out through the perineal incision. If it is small one may do nothing further in the abdominal cavity than repair the peritoneal floor, close the abdominal wound, and remove the growth by the perineal or parasacral method. If the gut must be cut across it should be done by an electroangiotribe, which not only sterilizes the gut wall, but seals it up so as to prevent any escape of fæcal matter into the abdominal wound. The amount of gut that can be excised and yet the sigmoid brought down into the anus is remarkable. I have twice removed over sixteen and once twenty-two inches of the sigmoid and rectum, and yet restored the normal fæcal outlet.

Treatment of intestinal ends.—The question of how best to dispose of the intestinal ends in extirpation of the rectum has long been one of considerable discussion. In the abdominal and parasacral methods the operation usually resolves itself into a resection, with two open ends of the intestines to be dealt with. Various methods have been employed in the series of cases which I now present, with the following results: The end to end suture has been employed in twenty-two cases, with four primary unions, sixteen cases of leakage with fistula and two deaths. The fistulæ have all healed eventually, but some of them have required as much as six or even nine months to acomplish this re-

sult. The Hochenegg method has been employed seven times, with four unions, one fistula, and three deaths. The Maunsell method has been employed twice, with a slight stricture in both cases, no fistula or death. In five instances the Murphy button has been employed to unite the ends; in four of these cases there was a fistula, with eventual closure, and one death. Colorectostomy has been employed four times, with excellent results in every case, barring a stricture at the junction of the colon with the rectum in two instances, which was very easily relieved by cutting through with pressure forceps. In the forty cases in which the perineal method was employed and the upper end of the gut sutured into the anus we obtained primary union in only seven cases, there were two deaths, and healing by granulation in the other thirty-one cases; there were seven or eight instances in which there were suppuration and fistulous tracts around the end of the gut, requiring secondary operation.

The period of confinement in the hospital following the different methods is a matter of interest, but not of vital importance. The cases of end to end union were invariably detained from two to six weeks longer than those in which the gut was sutured to the anus. The ultimate condition of the patient, however, is of more consequence. In the cases of resection, with end to end union, including all colorectostomies, there were twenty-two patients with perfect continence, and seven patients with partial incontinence, none of which was very severe. Of the cases in which the gut was sutured to the margin of the anus there were sixteen patients with perfect continence, thirteen patients with mild incontinence, and thirteen patients with almost

complete incontinence.

It would appear from these figures, therefore, that although the resections were accompanied by a higher mortality and longer detention in the hospital than those of amputation, the final results of the former are more satisfactory in the majority of cases than those of the latter. The discrepancy between these figures and the entire number is accounted for by those in which sacral and artificial ani were made. All the patients in whom the sacral anus was employed suffered greatly from incontinence. In one instance the patient's discomfort was so great that I was induced to make an inguinal artificial anus, from which the patient was infected and died from peritonitis. In the cases in which the inguinal artificial anus was employed the modified Bailey operation was adopted, and the patients usually managed them with comparative comfort.

Conditions Which Justify or Condemn Our Procedures.

Ultimate results.—Our crucial question: "Do our results justify continuance of our present methods in the treatment of cancer of the lower bowel?" must finally be answered by our immediate mortality, and by the ultimate results in those who survive the operation. The question of recurrence is an important one; but we must consider the condition of the patients during the time they live after the operation, even though they eventually die from recurrence. When we consider the pathetic condi-

tion in which most of these patients consult us, and the sufferings which those undergo who are not operated upon, we must ask ourselves what is the result to those who are operated upon, not only with regard to the length of life afterward, but also with regard to their state of health and comfort, whether

they have recurrence or not.

Pain.—Relief of pain is the first thing to be considered; so far as the immediate relief is concerned, the operation has proved effectual in almost every instance up to the time of recurrence or death from intercurrent diseases. It is an unusual thing to have to administer opiates in any form, except to control the bowels after these operations. The patients are almost without exception immediately relieved of all their former pains. The suffering from the wounds themselves is very slight. In many instances the patients who are addicted to the use of morphine previous to the operation have entirely discontinued it immediately thereafter. In one instance the patient was using thirty-two grains of morphine a day when he entered the hospital, and in three weeks had discontinued its use entirely, and never resumed it up to the time of his death, seven years later.

Continence.—The question of control of the bowels contributes so much to the comfort or discomfort of the patient that it is well worth while considering. Continence is comparative, and I have made an arbitrary division, as follows, perfect, good, partial incontinence, complete incontinence. By perfect I mean the normal condition of control. By good, the condition in which the patient, under a state of excitement or strain, is unable to control gases or liquid fæces. By partial incontinence, the state in which the patient cannot control liquid fæces sufficiently long to reach a convenient place for defæcation. By complete incontinence, the state in which the patient's bowels move unconsciously and without any control whatever. The results of my operations, according to this division, are as follows: Perfect continence, thirty-one; good connence, twenty-eight; partial incontinence, fifteen; complete incontinence, thirteen.

State of general health.—When we come to consider the state of the patients' general health following these operations, we must recognize that many are in a debilitated condition before they come for operation, and recuperate very slowly; a few of them never recuperate at all, notwithstanding the growth is removed and there is no recurrence; they go on in an indifferent state of health for indefinite periods, and eventually die from intercurrent diseases. We have had two instances like this in

our one hundred cases.

Again we have made an arbitrary division of the cases into excellent, comfortable, temporary improvement, and not improved. Under the heading excellent are included those patients who have gained health, strength, and weight, are relieved from their pains and able to enjoy life in their ordinary ways. Among the comfortable are classed those whose pains are relieved, who never become robust, and yet are able to carry on their usual vocations. Under the temporarily improved are those who are relieved of their pain and gain for a short time, but who relapse and die from recur-

rence or general debility. The not improved class are those patients in whom the tumor was not en-

tirely eradicated.

Among the eighty-seven patients who survived the operation, we find noted in our histories fiftyeight in excellent health up to the time of our last observation, twenty comfortable, five temporarily relieved, and four unimproved. Among those put down in excellent health are several who had later recurrences, but enjoyed perfect health for one to ten years after operation. Between the time of the recurrence and the operation, however, they were well to all intents and purposes, and enjoyed life as much as if they had never had anything done. Most of those in the "comfortable" class, however, eventually had recurrences; those temporarily improved all had recurrences. It is satisfactory to note that of the one hundred cases at least fifty patients have regained health, and were perfectly well up to the time of our last observation.

Causes of death.—The causes of death seem to bear out the generally accepted opinion that sepsis is the one thing to be feared. In our list of cases, with thirteen deaths, we find five of these (Nos. 7, 19, 40, 82, and 86) due to infection; two to shock (Nos. 14 and 40); two to embolism (Nos. 1 and 100); one to proliferating ulcers of the stomach (No. 78); one to sloughing of the sigmoid, due to insufficient circulation (No. 26); one to pneumonia (No. 58), which might probably be classed among the infections; one to secondary hæmorrhage (No. 73), caused by too tight packing of the wound.

The question arises, how many of these deaths could have been avoided? The two from shock were in desperate, almost inoperable condition, when the procedure was undertaken; we operated upon the insistence of the patients that they should be given the one chance for life that operation af-Those from infection might have been forded. avoided if our technique were as faultless in practice as in theory. Those from the other causes, such as pneumonia and embolism, are beyond the

control of surgical measures.

From this analytical study one might say that five out of the thirteen deaths might possibly have been prevented; the other eight were beyond the control of the surgeon, and yet they may be looked upon more as coincidences than as a necessary sequence. In a condition like this, however, in which the system is so insidiously undermined one must recognize that he is likely to meet with an average number of accidental intercurrent affections, such as we find in this list; and the most that we can hope to do is to control to a greater and greater degree the deaths due from infection.

The treatment of recurrences. This is a topic worthy of much study, and yet one which is nowhere treated of in literature so far as I can find. Of the twenty-one recurrences, I have operated the second time upon six patients, and three or four times in two. In two of these cases the recurrence took place in ten and five years respectively; and the secondary operations have given six and five

years further exemption.

In the other four patients the recurrences all took place under eighteen months after extirpation, and I do not think my secondary operations did anything but hasten the end. In brief, my experience leads me to believe that recurrence in less than one year will not be benefited by further operation; but late recurrences may be successfully removed.

The length of life after extirpation.—Upon this one point many will base their estimate of the results of operation. To set any arbitrary period of exemption as proving a permanent cure is not justified by experience. There is no period at which cancer may not recur. I have seen one recur ten years after operation. Every year of exemption, however, is another year of life, and it is interesting to see what we have gained for our patients in this respect. The average patient with cancer of the rectum dies in about twelve months after its discovery, unless operated upon. In the twenty-six patients of our series, who have survived the operation three years or more, the average length of life is six and a third years, with many of them still living, a gain for them of five years or more. sides this there were nine who lived, or are still living, between two and three years after the operation; and twenty-one between one and two years after it.

As instances of long exemption there are still living: One, sixteen years and ten months; one, fifteen years and ten months; one, twelve years and ten months; one, eleven years and three months; one, eleven years and two months; one, ten years; one, nine years; three, eight years; four, seven years; seven, five years.

(To be continued.)

THE ESSENTIALS OF VOICE PRODUCTION.*

By G. Hudson-Makuen, M. D., Philadelphia,

Professor of Defects of Speech in the Philadelphia Polychna III-pital; Laryngologist to the Frederick Douglass Memorial Hospital and the Chester Hospital, Chester, Pa.

Speech has been called articulated voice. Voice is the material of which speech is made. The first essential of speech production is adequate voice production.

I have ventured to define voice as a moving column of breath set in vibration by its own impact with the vocal bands and reinforced by its diffusion through the various resonance chambers into the surrounding atmosphere. The best methods, therefore, of setting the column of breath into vibratory motion and diffusing it through the resonance chambers into the surrounding atmosphere may be regarded as the essentials of voice production.

Two separate and distinct mechanisms are used in the production of voice, namely, the respiratory and phonatory mechanisms, and, not only must the different parts of each work in harmony but there must be also a complete coordination of the mechanisms themselves

The voice production for speech differs somewhat from the voice production for song. In the first place it differs subjectively. To the speaker the vocal effort is secondary to the articulatory effort, while to the singer the idea of vocality is paramount. The speaker is inclined to minimize the importance of voice production and the singer the

^{*}Read before the thirtieth annual congress of the American Laryn-gological Association, in Montreal, Canada, May 11 to 13, 1908

importance of articulation. The former often uses too little voice and the latter too little articulation. This tendency of the speaker to neglect his voice production leads to serious difficulties. In fact the great developmental defect of speech, which we call stammering or stuttering, has been shown to be due in the majority of cases to inadequate voice production, so that stammering may be called hypophonia rather than hyperphonia a term that Prof. Scripture

has given to it in a recent article.

Moreover, the voice production for speech differs somewhat from that for song in still another respect. The voice for speech varies more frequently than the voice for song, and it requires for its production more numerous and more rapid adjustments of the mechanisms. The sustained voice of song is rarely used in speech although it may be approximated in the strongly oratorical and dramatic roles. A greater volume of voice may be required for song but more numerous changes are used in speech. In song the voice is sustained and voluminous, while in speech it is inflected and more irregularly accented and emphasized.

The difference is more marked perhaps in the use of the larger muscles of the respiratory mechanism. The diaphragm, for instance, in singing is held in strong contraction during a greater period of time and the respirations are more prolonged, while in speaking the diaphragm and other respiratory muscles are constantly changing with the varying degrees of inflection, accentuation and emphasis.

But speech is something more than voice production. It is the product of the combined coordinate action of the two vocal mechanisms with a third, namely, the articulatory mechanism. In the production of speech we have combinations and complexities of finely coordinated movements such as are required in the exercise of no other bodily function. Each of the mechanisms employed has its own delicately coordinated action, and for the finished product, the three mechanisms themselves must be so accurately coordinated that there shall be complete harmony of action. To add to the complexity, and perplexity oftentimes, of the act of speech production we have the fact that the coordinate action of each mechanism, as well as their combined action is largely involuntary and automatic.

This brings us to a consideration of the so called central mechanisms of speech as distinguished from the peripheral mechanisms. The central mechanisms are those situated in the brain and spinal cord, and their function is, to set in motion and to control the peripheral machinery of speech and to coordin-

ate its various parts.

The cerebral speech mechanisms are situated in the left hemisphere and they are designated as follows: the auditory centre, in which are stored the memories for spoken words; the visual centre, in which are stored memories for written and printed words; Broca's centre, in which are stored memories for motor speech impulses; and the graphic centre, in which are stored memories for the movements of the hand in writing. Of these four centres the first two have been called sensory and receptive, and the last two motor centres, although as we shall see later on there are good reasons for supposing that they are all sensory centres and that the motor

centres are situated in the bulb and spinal cord. The chief receptive avenue for speech is through

the hearing. It is through this sense that the child gets his first impressions of speech, and it follows that when the organs of hearing are defective, the development of speech will be correspondingly impaired, and when there is absolute deafness, there will be absolute dumbness, until the child learns through special training to substitute for the sense of hearing the sense of sight, and to some extent also the sense of touch.

But a child who is not absolutely deaf may be mute, because the auditory speech centre constitutes only a part of the general zone of hearing in the left hemisphere of the brain, and if only the speech centre is defective or undeveloped there will be deafness only for speech sounds, or word deafness as it is called, while other sounds are distinctly heard.

Moreover, no two individuals hear speech sounds exactly alike because no two brains are exactly alike, and for the same reason no two individuals develop exactly the same kind of word images or speech

labits.

Next in importance to the auditory speech centre and closely related to it, is the visual centre, the region of the brain in which are stored memories for written and printed words. This centre is situated in the angular and supramarginal convolutions, and it is connected by commissural fibres with the auditory centre and also with the two so called motor centres which I am about to describe.

The chief motor, or Broca's centre as it is called, is situated in the posterior portion of the third frontal convolution, and in it are stored memories for the various movements used in the production of speech. The graphic centre is supposed to be situated in the posterior extremity of the second left frontal convolution and in it are stored memories

for the movements used in writing.

The fact that Broca's centre shares with the auditory and visual centres the function of serving as a store house for sensory impressions, has led Bastian and others to conclude that it is not a motor centre at all but a sensory centre, and that the motor centres for spoken words are represented in the medulla oblongata. Similarly it is asserted that the graphic centre, being a storehouse for the memories of movements of the hand and arm in writing,

is also a sensory centre.

This disposition of the cerebral mechanisms of speech, placing the sensory centres in the cerebral cortex and the motor centres in the bulb and spinal cord, seems to be the more scientific one because it accords more fully with both the physiological and pathological phenomena of speech production. Moreover, it has long been known that the centres for the coordination of the muscles and mechanisms employed in speaking and writing are situated in the bulb and spinal cord and it is only reasonable to suppose that the motor centres of these mechanisms should be in the same region of the nervous system. Bastian also gives to these hitherto called motor centres names that are suggestive of their functions. To Broca's centre, he gives the name glossokinæsthetic centre, and to the graphic, cheirokinæsthetic centre.

As I have said, it is through the ear that one

receives his first impressions of speech, and it is in the auditory centre that memories for spoken words are stored. The first step in the production of speech is a revival of these word memories in the auditory centre. This is effected either from without, by afferent impulses coming through the auditory and other nerves of special sense, or from within, by a process of silent thinking. These revived memories are immediately transmitted through commissural fibres to the glossokinæsthetic centre, where they in turn arouse previously stored memories for movements employed in the production of speech. Simultaneously there may be revived also in the visual centre memories for the movements of the vocal and articulatory muscles as seen by the eye, and this centre is also connected by means of commissural fibres with the glossokinæsthetic as well as with the auditory centre.

Although it is in the auditory centre that the revival of word images primarily takes place in most people, it occasionally happens that visual images are the first to come into the consciousness, and less often perhaps the glossokinæsthetic images. To the three classes of individuals thus characterized, Charcot gives the names, auditifs, visuels, and moteurs.

In the revival of word images, an important mental faculty is required, namely, that of attention, and in their externalization by means of articulate speech, the faculty of volition is employed. The exact anatomical connection between the willing to do a certain act and the act itself has never been satisfactorily explained. We only know that when one wills to speak, for instance, the act follows as a natural consequence, unless it is inhibited by other more powerful nerve impulses.

The order of cerebral activities in the production of speech, therefore, is, first, the revival of word images in the auditory centre (and in some cases in the visual centre) by means of afferent impulses from without through the special senses, or by means of impulses from the higher intellectual centres from within the brain; second, a transmission of impulses from these revived images in the auditory and visual centres through commissural fibres to the glossokinæsthetic centre; and third, a revival of the kinæsthetic word images, which in turn incites to action the motor centres in the bulb.

A word as to the development of speech in young children may throw some light upon this interesting subject. The first cry of the infant is the beginning of speech development. It is entirely automatic and reflex in its action, and its immediate purpose seems to be to expand the lungs and aerate the blood. It is not expressive of pain, because there is as yet no susceptibility to pain, and there is no psychic element in it, because the brain is wholly undeveloped. The young infant does not even hear himself cry, but as he grows older the nerve tracts leading to the brain gradually develop myelin sheathes which give to them the power of conveying sensations to their respective end stations in the cortex, and the child begins to feel, to see, and to hear. The crying now gives place in a measure to other sounds such as babbling, crowing, mimic reading, and echolalia, all of which are largely automatic and reflex, but more or less expressive of states of feeling. When the auditory nerve has become

medullated the child begins to hear. He hears, for instance, the word Mama, and he may repeat it in a mimic way, but it means no more to him than any other sound until he has learned to associate it with the individual for whom it stands, at which time it becomes registered in a portion of the general auditory centre as a word image, and this forms the beginning of distinguishing of the auditory speech centre.

When the nerve tracts leading from the motor centres in the bulb to the Rolandic area of the brain become medullated, the sensations produced by the musculature of the peripheral organs employed in crying, babbling, prattling, etc., begin to make their impressions in a definite portion of the general, kinæsthetic area, which portion is destined soon to become the glossokinæsthetic centre. In a similar manner the visual word centre and the cheirokinæs-

thetic centre are developed.

Just prior to, and synchronously with, the development of these special speech centres, however, we have the development of the higher intellectual centres of the brain. The child begins to understand speech before he begins to make use of it in a voluntary manner, but it is only after he begins to make use of it that its full import dawns upon him, and his intellectual faculties become thoroughly aroused.

An important period in the child's development is that of the transition from the involuntary babbling and prattling of meaningless words to the voluntary use of intelligent speech. The child now begins to assume a conscious control of the mechanisms of speech, and this involves certain mental faculties hitherto almost wholly unused. It is true the child begins to think before he begins to speak, but his thoughts are very superficial and rudimentary. Thinking and speaking are so closely related and so interdependent that the one can scarcely be carried on without the other. "To think" says Max Müller "is to speak low, and to speak is to think aloud." However, the higher intellectual centres now take command, as it were, of the lower speech centres, and through them also of the peripheral mechanisms of speech, and actually train them into more or less healthful physiological activity. This task of training the speech centres is conducive also to the healthful activities in the intellectual centres, and thus they react beneficially the one upon the other, and the highest development of either is impossible without a corresponding development of the other. Defective speech, therefore, is naturally suggestive of defective mentality, and defective mentality is always accompanied by defective speech.

My purpose in presenting this paper has been not to herald any new or original theory but rather to give a brief résumé of the anatomy, physiology, and psychology of the mechanisms employed in the production of speech, and in summing up the essentials of speech production, therefore, I would say, first, that the mechanisms must be structurally normal and free from pathological encumbrances, such as dental, alveolar, and palatal irregularities, enlarged tonsils, nasal obstructions, and cerebral tumors; second, the various parts of the individual mechanisms must be accurately coordinated, and there must be a similar accurate coordination of the mechanisms themselves; and, third, this accuracy of vocal

and articulatory musculature must be largely automatic, and this in turn is brought about mainly through psychophysical development and training.

1627 WALNUT STREET.

TUBERCULIN AS AN ADJUNCT TO THE HOME TREATMENT OF PULMONARY TUBERCULOSIS.*

By James Alexander Miller, M. A., M. D., New York,

Director of the Bellevue Hospital Tuberculosis Clinic.

The use of tuberculin in its various forms for the treatment of tuberculosis has been receiving so much attention in the last few years that it would almost seem that a definite opinion of its value should have been reached. The very great majority of the reports published upon this subject, however, have come from sanatoria and health resorts, where the patients reported have received also the usual hygienic dietetic treatment combined with the influence of a favorable climate. Moreover, the larger number of these patients have been in the early and more favorable stages. The fact that patients under such conditions usually do well without the use of tuberculin has led to considerable skepticism upon the part of many as to the real value of the higher percentage of good results reported from the use of tuberculin.

Although all of these reports agree in a very striking manner in showing a considerable advantage for the tuberculin treated patients in the results of the immediate treatment and in the stability of these results, it is nevertheless evident, that a much more severe and unimpeachable test of the value of this treatment would be the results obtained with cases treated at home under more or less unfavor-

able surroundings.

A few such reports have been published, but they are not entirely conclusive, and this present contribution is made in the hope of adding something to our knowledge of this aspect of the tuberculin question.

About four years ago, the writer, through the influence and under the supervision of Dr. E. L. Trudeau, became interested in the therapeutic use of tuberculin, and ever since that time has had constantly a certain number of cases under this treatment in New York.

Number of Cases.

During this time ninety-four such patients have been observed. Of these forty-eight were under treatment less than three months. As this is too short a time upon which to base any reliable conclusions, these cases are excluded, leaving forty-six patients who have been treated three months or more as a basis for this report. The average duration of treatment of these forty-six patients was six months.

The large number of patients treated less than three months is chiefly interesting to demonstrate the difficulty of keeping dispensary and hospital patients under continued observation for the length of time necessary for this form of treatment.

Of the forty-eight patients, thirty-six simply dis-

*Read before the American Climatological Association, in Boston, June 9 and 10, 1908.

appeared from observation; of the remaining twelve, five refused to continue, four became acutely ill, and three showed marked intolerance to tuberculin.

Conditions under which the Patients were Treated.

These forty-six patients were treated under the

following conditions:

I. At the Bellevue Tuberculosis Clinic, where the patients have been of the poorer classes, living in tenements, with no better care than the efforts of the visiting nurses, or the assistance that some chartable society could provide; twenty-one patients were treated here (45.7 per cent.).

2. In a tent pavilion on the Bellevue Hospital grounds, where the patients were under constant supervision, were well fed, their habits carefully regulated, and were practically in the open air all of the time. Only two patients were treated here (4.3)

per cent.).

3. At the Seton Hospital, which is situated at Spuyten Duyvil, in the borough of the Bronx, New York. There the patients are under the usual hospital régime, with no special diet, and were out of doors, but not under the strictest supervision, for a good share of the time. Nine patients were treated

at Seton (19.6 per cent.).

4. As private patients some were treated at my office. These patients consisted for the most part of cases which had been under observation for some time with no improvement, very often having returned uncured from health resorts, having been compelled for various reasons to come back to live either in or near the city. Such patients have usually had good home conditions, good food, and a very fair amount of the open air treatment, this depending, of course, upon the various individual circumstances. There are fourteen such patients in this series (30.4 per cent.).

A summary of the living conditions of all patients shows twenty-seven to have been living under conditions which might be called good, sixteen under fair,

and three under distinctly poor conditions.

Of all patients, fourteen (30.4 per cent.) were working and earning a livelihood during the course of treatment, and seven (15.2 per cent.) others were women who were performing their usual housewife duties, making a total of 45.6 per cent. of patients who were living an active life at that time, and leaving 54.6 per cent. of patients who were resting as a part of their treatment.

It will be noted, therefore, that the living conditions represented in the cases here reported are fairly typical of those under which tuberculosis is en-

countered in any large city.

Selection of Cases.

Three main principles have guided our selection of cases: I. No early or favorable cases for whom sanatorium or other climatic treatment was available were kept in New York. 2. No cases with fever were treated, with two exceptions. 3. Tuberculin treatment was urged only for patients who were not progressing favorably without it.

Class of Cases Treated.

As a result of these three principles the patients treated have been largely long standing advanced cases, who were gradually drifting into more or less chronic invalidism.

Only six cases were incipient (13 per cent.);

twenty-seven (58.7 per cent.) were moderately advanced, and thirteen (28.3 per cent.) were far advanced cases. The average duration of the disease before beginning treatment was 19.8 months.

Seventeen patients (36.9 per cent.) had had previous climatic treatment, and of these five had begun their tuberculin treatment before returning to New York. Thirty-four patients had no complicating conditions, eight had complications of a tuberculous nature, and four had nontuberculous complications. All but three had bacilli in their sputum.

It can hardly be said that this material, under the living conditions which have been described, is overfavorable for any kind of treatment, but it would seem that it should offer an excellent opportunity to judge of the actual value of the tuberculin treatment through the exclusion of many other factors.

Varieties of Tuberculin Used.

Three preparations of tuberculin have been used in this series of cases: I, Koch's original tuberculin (O. T.); 2, bacillus emulsion (B. E.); 3, Denys's bouillion filtré (B. F.).

The old tuberculin was used during the earlier part of the work, six patients in all, but has, in the last two or three years, been used very little.

Bacillus emulsion was used considerably at first, and was then largely discarded in favor of the bouillion filtré; but more recently, during the last few months, it has been used again considerably. Seven patients were treated by B. E., and four were treated partly by B. E. and partly by B. F.

The bouillion filtré has been used continuously during the last two years, and for one year was used almost exclusively, with a total of twenty-nine pa-

tients or sixty-three per cent. of all.

Experience with these preparations has led to the conclusion that there is really very little difference between them, either in their effects or in their method of action. This is particularly true of the bouillion filtré and the old tuberculin. The difference in the method of preparation of these two varieties of tuberculin would lead to the assumption that the old tuberculin was stronger. This, however, is not warranted by experience, and it would seem that these two preparations can be considered to be about equal in strength.

The bacillus emulsion acts somewhat differently from the other two in its liability to produce unexpected reactions. This, however, is probably often due to faulty emulsification and can easily be

obviated.

It has seemed, however, that in strength it can be compared, dose for dose, with the other two preparations, only when the dose is computed by volume, i. e., I c.c. of O. T. or B. F.=I c.c. of B. E., thus climinating the method of computation upon the basis of the solid substance contained in the emulsion.

I believe that bouillion filtré is better in patients who show an oversusceptibility to tuberculin, and it is therefore now used in all such patients and also in the few patients who have had chronic fever during the administration of tuberculin.

Dosage.

During the first two years the dosage employed was according to the plan recommended by Moeller and others, beginning with 0.00001 gramme or 0.0001 gramme, and increasing by doubling the dose at each injection at intervals of three days.

In the patients who stand this treatment well, the effects are apparently very beneficial, but there is a considerable number of patients who quickly become intolerant, and in whom reactions of greater or less severity occur. I feel sure that in some of these patients harm was done rather than good.

During the past two years the decimal system of solution advocated by Denys and Trudeau has been employed, beginning with a dose of 0.0000001 gramme, and progressing by two injections a week up to a maximum dose of 1.0 gramme. This plan has been found very satisfactory, excepting that it has been found necessary to diminish the first few doses of each higher dilution in order to avoid reactions.

One gramme has been looked upon as the maximum dose to be attained in any given case. This amount, however, is purely arbitrary, and in many cases it has seemed both undesirable and unnecessary to try to push the dosage up to that point.

Often it is better to make 0.1 gramme the maximum dose and to go higher only in those patients who tolerate these large doses well and in whom it seems desirable to obtain greater degree of immunity. In some patients 0.001 gramme is the maximum dose that can be attained without producing intolerance.

I have therefore come to believe that each patient is a law unto himself in this respect, and to consider each patient separately in deciding as to the maximum dose desirable. In a general way, however, I would put the limits of maximum dosage

from 0.01 gramme to 1.0 gramme.

In our patients twenty-two received a maximum dose of more than 0.001 gramme and twenty-four a maximum dose of less than that amount.

The time required to reach this dosage is at least six months, and is often a year or more. The time element in the treatment is probably just as important, if not more so, than the absolute dose of tuberculin administered. The average duration of treatment in our cases was six months.

Guides to Dosage.

We have adhered strictly to the general principle of avoiding as far as possible all constitutional reactions to the tuberculin.

The clinical method.— The so called clinical method of determining the proper progression of dosage has been the usual one employed, and with sufficient experience this method is very satisfactory.

Too great emphasis, however, cannot be placed upon the importance of watching closely for slight evidences of intolerance to tuberculin, as shown by slight malaise, loss of appetite, headache, moderate loss of weight, etc., even when no febrile reaction has been produced.

Increased cough and expectoration, pains in the chest, and even slight hæmoptyses are evidences of a focal reaction in the lungs, and must necessarily

be considered carefully. I do not feel, however, that such reactions if slight show the same tendency to intolerance as do the slight constitutional reactions, and it has often seemed as though a very slight focal reaction was beneficial. We are here treading, however, on very delicate ground, and the exercise of additional care is necessary in these cases, for, of course, any considerable focal reaction is not only undesirable, but may be even dangerous.

The local reaction at the point of injection should be considered, there usually being no disturbance beyond a slight sensitiveness for a few hours. Appearance of local pain, redness, or swelling of any considerable duration is, in our experience, an indication of an approach to the limit of tolerance, and should be so considered in estimating the proper

progression of dosage.

Patients with any tendency to constitutional reaction were given a rest from the treatment for several days or more, and then either the same dose repeated, or some fraction even as far down as o.I of the preceding dose given, depending entirely upon the severity and the duration of the reaction that had been produced.

In a general way a mild constitutional reaction protracted over several days is probably more serious than a sharper reaction, which quickly disappears. A new injection was never given until all signs of reaction have been absent for several days.

In over 2,200 injections given in this series of cases we produced fifty-one constitutional reactions in twenty-eight patients. Eighteen patients had no reaction at any time. Of the fifty-one reactions only eight were severe, twenty-nine were moderate, and

fourteen slight.

The opsonic index.—For several months Dr. Park and Dr. Bolduan, of the Health Department Research Laboratory, made systematic determination of the opsonic index in many of our cases under treatment with tuberculin. The results obtained were so absolutely contradictory and unreliable that it seemed to us all that it was impossible to rely in any way upon the opsonic index as a guide in the tuberculin treatment of pulmonary tuberculosis.

Arneth's neutrophile blood picture.—For more than a year a systematic study of the neutrophile leucocytes in the blood has been made at the Bellevue Clinic by Miss Margaret Reed, Instructor in Biology in Columbia University. This study has included patients suffering from all forms of pulmonary tuberculosis and especially those who have been under treatment with tuberculin. We have come to the conclusion that the distinctive determination of the nuclear forms found in the neutrophiles of the blood is a very valuable guide to the resistance of a patient to tuberculin and of the approach to a condition of oversusceptibility to this agent, and that it is therefore very helpful in conjunction with the clinical manifestations of the case. It is also very valuable in prognosis.

Results.

In the forty-six patients under consideration, the following results have been obtained: Four patients (8.7 per cent.) were apparently cured; eleven patients (23.9 per cent.) were arrested; nine patients (19.6 per cent.) were improved: eleven patients

(23.9 per cent.) were stationary; eleven patients (23.9 per cent.) were progressive.

It will thus be seen that twenty-four patients (52.2 per cent.) showed an improvement and twenty-two patients (47.8 per cent.) were unimproved.

A further analysis of these results shows that 83.3 per cent. of the incipient cases, 44.4 per cent. of the moderately advanced cases, and 53.8 per cent. of the far advanced cases improved. The higher percentage in incipient cases is to be expected, but the number of cases is so small that the results are suggestive rather than conclusive. That a larger percentage of the far advanced cases should be improved than of the moderately advanced, is not explained, but in any event that is not as noteworthy as is the fact that 47.5 per cent. of combined advanced and far advanced cases show improvement. 57.1 per cent. of the office patients improved, 42.8 per cent. of the clinic cases, 100 per cent. of the tent cases, and 55.5 per cent. of the Seton cases. As there were only two tent cases, the results there are of little value. That the dispensary cases should show the lowest percentage of improvement is undoubtedly due to the poorer living conditions of these patients.

The average duration of disease of the improved cases was 12.3 months, and of the unimproved cases was 29.7 months. This was undoubtedly a very appreciable factor in influencing the results of treatment.

The average duration of treatment was 6.4 months in the improved cases, and 5.1 months in the unimproved. This difference also probably exerted considerable influence upon the results.

Of the different varieties of tuberculin used, the O. T. shows the highest percentage of improvement, 83.3 per cent., but this was only in six cases; B. F. shows 51.7 per cent. of improved cases; B. E. 42.7 per cent., and combined B. E. and B. F. 25 per cent. This last method of combined treatment was only used when a patient was not doing well, so that the low percentage is not surprising. There seems to be little difference in results between B. F. and B. E., whatever there is being in favor of the former, and it would certainly appear that O. T. was at least as effective as either.

Of the patients who had had previous climatic treatment 52.9 per cent. improved, and 47.1 per cent. did not. This fact is interesting, but probably means little as almost all of these patients were very chronic cases.

Of the patients who worked during the tuberculin treatment, 42.8 per cent, were improved, and 57.2

per cent. were unimproved.

Of the patients who rested during the treatment 60 per cent. improved, and 40 per cent. did not. It is worthy of note, that so many of these patients were able to work, and still did well, although the advantages of rest are manifest from our figures, as might be anticipated.

The Present Condition of Treated Cases.

We have been able to ascertain the present condition of all of the patients in the series excepting three. Of the four apparently cured patients all are now well and working. Of the eleven arrested cases, nine patients are well, and of these, five are work-

ing, one is dead, and one is untraced. Of the nine improved cases, two patients are well and working, three are fairly well, two are dead, and two are untraced. Of the eleven stationary cases, one patient is now well, nine are fairly well, and of these five are working, one patient is doing badly. Of the eleven progressive cases, one patient is now fairly well and working, three are doing badly, and seven are dead.

It will thus be seen that of all the patients, sixteen (34.8 per cent.) are now known to be well, thirteen (28.4 per cent.) are fairly well, four (8.7 per cent.) are doing badly, ten (21.7 per cent.) are dead, and three (6.5 per cent.) are untraced. Seventeen per cent. of these patients are now working. Of the twenty-four patients which-showed improvement at the end of the tuberculin treatment, fifteen are well, three are fairly well, three are dead, and three are untraced.

Of the twenty-two patients who did not improve under treatment, one is now well, ten are fairly well, four are doing badly, and seven are dead.

Conclusions

We do not feel that even four years' experience is sufficient to warrant any absolute conclusions as to the therapeutic value of tuberculin. The results of any method of treatment in tuberculosis are influenced by innumerable factors which may very easily mislead the most conscientious observer. Statistics are probably of little real value under such circumstances, less so perhaps than the gradual accumulation of clinical impressions from continued study.

As far as statistics go it would seem that any form of treatment must have considerable efficacy which is able to show the improvement in condition, with such a degree of permanency in such a class of cases, and under such conditions as are here reported.

As to clinical impressions, our experience has included several patients in whom the results of the tuberculin appeared truly remarkable, in some others, there has been distinct disappointment especially in a few which seemed at first to do exceedingly well, and then relapsed later, just as is customary in tuberculosis, but which we would hope not to find when any degree of immunity had been established.

It cannot be too strongly emphasized that if good results are to be obtained by therapeutic use of tuberculin, the greatest patience and care must be exercised in every particular. The dilutions should be made only by some one who is skilled in such work. Any evidence of intolerance must be carefully noticed, and the progression of dosage correspondingly regulated; and lastly and perhaps most important the duration of treatment must be extended over a very considerable time, preferably from six months to a year.

The sum of our impressions and results lead us to the opinion that we have in tuberculin an active and useful aid in the treatment of pulmonary tuberculosis, which, while not truly specific, is probably a distinct step in that direction. We are, therefore, encouraged to continue its use in suitable cases, and shall do so until some better specific agent is available.

I wish to acknowledge my deep indebtedness to Dr. E. L. Trudeau for his continued and invaluable advice and encouragement in every step of this work, and through him to the Saranac Laboratory for the supply of tuberculin which has been generously placed at my disposal.

18 West Fifty-first Street.

THE CONJUNCTIVAL TUBERCULIN TEST.*

By George Mannheimer, M. D., New York.

This test and this reaction ought to be called conjunctival test and conjunctival reaction. The term ophthalmoreaction is a misnomer, half Greek, half Latin, and besides it is not to the point. The reaction takes place on the conjunctiva, and not in the eye. The test should not be called Calmette test. Calmette is not the originator of it. Wolff-Eisner, of Berlin, first employed and described it. To him belongs the credit of having first used the conjunctiva for the diagnostic application of tuberculin. That was the new departure. Wolff-Eisner was led to it by his studies on hay fever, in which disease the conjunctiva is peculiarly sensitive to the toxines of certain pollen.

Tuberculin has been and is being applied in various ways for diagnostic purposes. The hypodermic method is Koch's original one, and is most widely used. But it has also been administered per os in solution or in keratin coated pills, per rectum as enema or suppository, by intracheal injection, by

inhalation, and by inunction into the unbroken skin. Lately the methods of applying it to small skin scarifications (von Pirquet) and to the conjunctival sac (Wolff-Eisner, Calmette) have come into extensive use. The literature on the subject is already very large. This testifies to the great interest these new reactions have aroused in medical circles. Physicians are becoming more and more impressed with the enormous frequency of tuberculosis and with the great importance of recognizing it early. They also know the shortcomings of physical diagnosis and the difficulties of arriving at a positive diagnosis in many cases, and therefore welcome any new method that bids fair to help along these lines.

Diagnostic injections of tuberculin have not become popular, although they are used now much more frequently than ten and fifteen years ago. The principal objections to them, from a purely practical standpoint, are: First, patients are made ill, or at least very uncomfortable, by the general fever reaction; second, the temperature has to be taken every two or three hours for several days before and after the injection; third, the test cannot be applied when

there is fever.

The conjunctival test obviates all these objections. It is simple, easy of application and observation: there is usually no general reaction; patients usually do not suffer from it; and the presence of fever is no hindrance.

A few words as to the technique. The lower lid is drawn down, while the patient is directed to look up; or it is pulled forward away from the bulb, and a drop of the tuberculin solution is dropped into the groove thus formed. Or the patient is directed to look downward, and the solution is dropped on the bulb; from there it flows down into the lower sac. The drop should not fall from a great height, but the dropper should not come in contact with the lid. In cold weather the dropper should be slightly warmed. The lid must be held for at least half a minute, to allow the drop to be distributed along the conjunctival sac. If these precautions are observed, the drop is not likely to be squeezed out at once by reflex contractions of the orbicularis muscle. patient should be warned not to wipe the eye, and not to touch the other eye. He should avoid exposure to wind, dust, and smoke as much as possible.

The symptoms of a reaction appear in from three to twelve hours in most cases, but may be delayed twenty-four to forty-eight hours. They are a scratchy feeling, lachrymation, redness, and swelling of the inner canthus, then of the conjunctiva of the lower lid, which may increase and include the entire conjunctiva, with œdema of the lids.

The reaction usually disappears within two, three, or four days, but may last a week. I have seen it last eighteen days. Patients are usually not inconvenienced, some not even with third degree reactions. Others complain of pain in the eye and head.

There are occasionally nasal symptoms, clogging up or increased secretion of the side of the nose corresponding to the instilled eye.

Very rarely general symptoms are observed, e. g., slight rise of temperature and malaise.

A physician, thirty-eight years of age, was treated for tuberculosis of the right apex when seventeen; he remained tuberculosis of the right apex when seventeen; he remained well up to three years ago; then he had a hæmoptysis and a left pleuritic effusion. He made a good recovery, and has continued in active practice until the present time. In November, 1907, he received a drop of tuberculin in his right eye, which did not react. Ten days later he received a second instillation in the left eye, and reacted markedly. While the conjunctivitis subsided, his left nostril closed up and later began to discharge, he felt grippy. coughed and expectorated a little, had pain in the left lower chest, the site of his former pleurisy, a morning temperature of 100° F., evening temperature of 100.6° F. This condition lasted for nine days. He states that after this incident he felt as if he had recovered from a severe illness, and altogether much better than for a long time previous. He thinks the inoculation benefited him.

Of course, in this case some of the tuberculin was absorbed into the general circulation, which is exceptional. This absorption takes place also in those rare cases in which a slight reaction occurs simultaneously in the uninstilled eye, provided, of course, that transmission by the patient's fingers can be ex-

A young girl in the Bedford Sanatorium received a drop A young girl in the Bettort Saintorium received a dioperate reaction on January 14th, at 7 p. m. She showed moderate reaction the next morning. On the 16th, while the conjunctivitis was on the wane, she complained of pains in the left side, shoulder, and back, and had an evening rise of 101.4° F. But menstruation had come on the previous night. She had had similar short rises before.

The case is therefore not unequivocal. Tuberculous women often have præmenstrual, menstrual, or postmenstrual fever. It is perhaps worth while investigating whether tuberculous women or suspects, who are known not to have these rises, get them when tuberculin is instilled just prior to menstrua-

Contraindications are any existing disease of the eyes, except errors of refraction, or any tendency thereto; or traces of previous disease; scrofulous children; hay fever; ordinary colds; perhaps also the administration of iodides. If we follow these rules, we probably will have no untoward effects.

A patient in the Bedford Sanatorium received a drop and had a very severe reaction. He had headache the whole second night after instillation. It was found later that he had had a conjunctivitis ten days previously. If this had been known the test would not have been made so shortly afterward.

^{*}Read before the Medical Society of the County of New York, May 25, 1908.

A few patients who were taking potassium iodide showed a reaction, although they presented no clinical evidences of tuberculosis. Since iodides produce conjunctival hyperæmia in some individuals, it is better to omit the test during their administration.

A number of cases have been reported in which more or less serious effects resulted from the installation. Phlyctamulæ are the most frequent, but generally the least serious, complications. They occur chiefly in children. But corneal infiltrations and ulcerations, and affections of the uveal tract, have been observed. A few bad cases occurred in this city. One is reported in the Archives of Ophthalmology, March, 1908:

A girl, nine years of age, had scrofulous superficial keratitis of the right eye. She received a drop of tuberculin into the left, apparently sound, eye. A severe local reaction followed, accompanied by a mild general one. Ten days later marginal corneal infiltrations appeared in the eye instilled, which slowly ulcerated and spread, but which are now healing after five months' duration. In this case the tuberculin should not have been used. I suppose the author would not try the experiment again in a similar

A man, fifty-two years of age, in one of our large hospitals, suffering from pulmonary tuberculosis, and a cervical Potts' disease, in poor general condition, received 2 mm. of a one per cent. precipitated tuberculin. With a severe local reaction, there developed corneal infiltration and a phlyctenula; no pain, no fever. Recovery was complete. No bacteriological examination of the conjunctival secretion was made. This ought to be done in all such cases, and would probably reveal the fact that most of these corneal complications are due to secondary infections with pneumococci or pus cocci.

These accidents may be prevented by treatment. We should treat all pronounced reactions the same way we treat any other severe conjunctivitis.

Sometimes the tuberculin is held responsible for effects which are post hoc, not propter hoc:

A trained nurse, twenty-four years of age, in apparently perfect health, submitted to the test on a Monday afternoon. The eye became red the same evening. Next day she did not feel well, but attended to her duties. The reaction was moderate. On Wednesday evening she took to her bed with a temperature of 102° F. She developed a typical coryza, sore throat, hoarseness, cough, and expectoration She was sick for a week.

This was to my mind a simple case of catarrhal grippe which had nothing to do with the tuberculin instillation. The latter was simply made during the incubation of this infection.

I dwell on the unpleasant sequelæ of the test to show that it is not harmless, but also that some of these sequelæ are preventable. In my experience of about 350 instillations, no harm resulted. I have seen no involvement of the eye proper. The few severe reactions which I have observed all passed off without mishap. They all occurred from the use of a one per cent. solution of precipitated tuberculin

Now, a few remarks as to the preparation: Theoretically it makes no difference what preparation of tuberculin we use, if it only contains soluble toxine. Wolff-Eisner and his followers use the old Koch's tuberculin in one, two, four, or five per cent dilusions, with normal salt or boric acid solution. Calmette thought the glycerin and beef salts contained in the T. O. could alone give rise to conjunctival irritation and inflammation. He therefore precipitated the T. O. with 95 per cent. alcohol, and washed the filtered sedment with 70 per cent. al

cohol, dried, and pulverized. He dissolved the powder in sterile normal salt solution to make one per cent. This whole procedure, which, by the way Koch had already employed to purify his tuberculin, is unnecessary for the purposes of the test. Besides, it makes it more expensive. The infinitesimally small amount of glycerin and salts contained in one drop of a one per cent., or even five per cent., solution of T. O. does not irritate the conjunctiva. Control tests with much stronger glycerin and salt solutions amply verify this. The T. P. (precipated tuberculin) is not a uniform preparation. It varies much, according to the method of manufacture. The relative strength of a one per cent. T. O. and a one per cent. T. P. is variously given as a 1 to 2, I to 3, or I to 7. The T. P. is probably too strong in one per cent. solutions. The two cases of corneal complications, and all my severe reactions, resulted from its use. There is a movement on foot in this country to have one uniform standard preparation of T. O. for all the tests, a one per cent. or two per cent. solution for the conjunctiva, a ten per cent. or twenty-five per cent. solution for the skin. Results can then be compared much better than heretofore.

It may be possible that some nontuberculous individuals react to these strong dilutions, whereas they would not react to the ordinary dosage to which a tuberculous person usually reacts. Still there is nothing to prove this, except the analogy of the hypodermatic test. Almost every one is supposed to react to the hypodermatic injection of 10 milligrammes or more of T. O.

Calmette used bovine tuberculin. This complicates matters slightly. I think it best, for the present, to use human tuberculin only for the conjunctival test. Detré's investigations on differential cutaneous reactions are highly suggestive and ought to be followed up.

Now, as to the theoretical explanation of the reaction: It is a reaction of immunity, and more especially of sensitization, of oversusceptibility. The tuberculin, which is a specific proteid of the tubercle bacillus, or at least which contains this specific proteid, when dropped into the eye, penetrates the epithelial layer, and is slowly broken up into its constituent parts by the connective tissue cells. In a person who is free from tuberculosis these cells have not been sensitized and the process of breaking up the tuberculin proteid is slow, and consequently there is no reaction. The specific proteid is broken up by the elaboration in the connective cells of a specific ferment. This makes the cells acted upon sensitive. When the second instillation is made into the same eye in an individual free from tuberculosis this ferment which is already formed as the result of the first instillation, acts rapidly, and the result is an inflammatory process. On the other hand, when one has tuberculosis, the tubercle bacilli have broken down in the body, the connective tissue cells of the eye, and possibly of every other part of the body, have already been sensitized, the ferment is present, and the first instillation gives the inflammatory process.

Again, in advanced tuberculosis there is no reac-

[&]quot;It is, perhaps, accessful to experiment with both kinds of tuber culm on the same orderedual some cases may react to boxine and my indimum, tubes often now by thereby by a cognized as boxin

tion, because the cells are continually kept in an exhausted condition from the tuberculin, which is constantly present in the blood of such an individual.

This explanation, which comes from no less an authority than V. C. Vaughan, of Ann Arbor, seems to explain most, if not all, of the phenomena, as we observe them in practice. The majority of tuberculous individuals, e. g., incipient and moderately advanced cases, react promptly. The majority of far advanced cases do not react. Miliary tuberculosis, tuberculous meningitis, which is a part of a generalized tuberculosis, and cachectic cases, do not usually react.

A child, two years old, with tuberculous meningitis, in the wards of Lebanon Hospital, presented a marked œdema of the upper lid, three days after instillation, but no conjunctival hyperæmia.

Eyes instilled for a second time react in about

seventy-five per cent. of all cases.

A second instillation into the same eye has, therefore, no diagnostic value. It may, perhaps, indicate whether the first instillation has been efficient as to dosage, preparation, and technique. This sensitization is known to last fifty-one days. It requires a few days to make its appearance.

A number of apparently nontuberculous persons

react.

Thus a positive result does not necessarily mean tuberculosis, and a negative result does not exclude it. We should explain to our patients that a positive result need not frighten them, nor a negative result

lull them into a sense of false security.

Some physicians have abandoned the test, on these grounds, as unreliable. It certainly is not a sure thing; but then we have no absolutely pathognomonic symptoms in medicine. None of these biological tests are absolute; they cannot be expected to be so. Every organism has a relative amount of immunity to all kinds of infections and intoxications. Normal serum has the power of neutralizing, to a certain extent, many different poisons.

Positive results have been obtained in convalescents from typhoid fever. These patients seem susceptible to all kinds of bacterial proteids. Cases of leprosy and syphilis have reacted. These individuals may have substances in their system which have the power to react in a manner similar to that exhibited

by a tuberculous individual.

But then, again, the subject of latent tuberculosis has to be considered. How many of those, clinically not tuberculous, but reacting, have latent tubercu-

losis?

Autopsies on persons dying from other diseases and not suspected of tuberculosis, but giving a positive conjunctival reaction during life, have not been as thorough as would be desirable in order to clear up these points. Nägeli found healed or active tuberculous foci in ninety-six per cent. of adults in a large city, dying from other causes, and not suspected of tuberculosis. His methods at the autopsy ought to serve as an example.

We have to distinguish between active and inactive latent lesions. Wolff-Eisner asserts that the cutaneous test reveals the latter, the conjunctival test the former. The two tests should therefore be

used together.

The results of the conjunctival test are usually

corroborated by a subsequent hypodermatic test. With each injection of tuberculin a former conjunctival reaction which may have long subsided is often rekindled. The eye may become red before the appearance of the general reaction, and even without it. A number of my patients have shown this phenomenon.

The nurse, whose history I have reported, had a cold state weeks after the first one, and with it her former conjunctival reaction reappeared, without her having again come in contact with tuberculin. She is apparently not tuberculous, but her mother died from phthisis, and she herself, through her work in a large dispensary, is constantly exposed to infection.

It might be worth while to test systematically the employees of tuberculosis dispensaries.

A number of my doubtful or suspicious cases, which reacted, have since been proved by other signs to be tuberculous:

A young, healthy looking woman, twenty-four years of age, of good family history, complained last December of pain in various joints, but principally in the right thigh and knee. The region of the hipjoint was tender. Pain and tenderness rapidly increased; no fever, no other signs. Antirheumatic treatment was without effect. The diagnosis lay between a tuberculous or gonorrheal coxitis, a neoplasm, or a neurosis. The conjunctival test was positive, even severe. Fixation of the hipjoint in plaster afforded immediate relief. On March 1st, 0.001 mg. T. O. was injected for therapeutic purposes, followed by a rise of temperature to 100.6° F. A slight cough, which had previously been present, increased. After three days the same small dose was injected. The temperature rose to 100.6° F. Since then patient had slight elevation of evening temperature, and her cough slightly increased. Physical examination, April 14th, showed changes of breathing and scanty râles in the right apex. Bacilli were found on May 16th for the first time. The patient had nursed a consumptive relative six months before.

This case shows the extreme sensitiveness of fresh infections to tuberculin.

A man, thirty-three years of age, was sent to me by a laryngologist, who found an ulceration in the interarytenoid space and on suspicion had the sputum examined, with positive findings. The patient had slight cough for eight weeks, his voice was husky and tired easily. My physical examination was entirely negative. The conjunctival test was negative. A second sputum examination by the same laboratory proved negative. The ulcer has healed in a remarkably short time. The laryngologist now thinks that it was probably catarrhal, and the first sputum examination possibly erroneous.

I have a few cases of diabetes and of pleuritic effusions where a positive conjunctival test was later corroborated by distinct clinical signs of tuberculosis.

I have obtained the greatest help from the reaction in doubtful or suspicious cases. Here a positive result serves as a valuable pointer. Wolff-Eisner and Stadelmann point out the great prognostic value of the test. They distinguish a normal, a faint and fleeting, and a prolonged or delayed reaction, and ascribe to each of these types prognostic significance.

If an incipient or moderately advanced case of pulmonary tuberculosis shows a faint, fleeting reaction, the chances are that the case is progressive. The disappearance of a previously marked reaction on a subsequent instillation into the other eye is probably a bad omen. The organism has lost one of its defensive agents—the power to react. My observations have not been sufficiently extensive or prolonged to prove this prognostic value.

A word as to the repetition of the test in the same

case. The same eye should not be used a second time, as mentioned before, but an instillation may be made into the other eye with the same or a stronger solution, after the lapse of a few days, if the first reaction was negative or doubtful. This second test has not quite the same diagnostic value as the first. As a matter of precaution, patients should be questioned before an instillation whether they ever had the test applied before.

Solutions of T. O. or T. P. should not be kept longer than a week. They even deteriorate in sealed capillary tubes in the course of a few months.

A positive reaction does not locate the disease.

Several children in a family had the grippe. They all recovered promptly except one, who continued to run down, have fever and cough. A consultant found diminished breathing over one lower lobe and in view of this history suggested the possibility of an acute tuberculosis. He advised a conjunctival test. A marked positive reaction occurred He then made a positive diagnosis of acute pulmonary tuberculosis. The child recovered within ten days. The child might have had a tuberculous focus somewhere, but the lung condition which prompted the test was apparently not tuberculous.

I know of this case from hearsay only.

All tuberculin tests are deficient in this respect, they can only give corroborative evidence; they form only one link in the diagnostic chain.

Now as to my observations. I have records of

350 tests in 260 people.

They were observed at the Mt. Sinai Hospital Dispensary; at the Bedford Sanatorium; at the Virginia Sanatorium for Consumptives; Ironville, Va., by Dr. Junger; at the Lebanon Hospital, and in private practice. I am indebted to my associates in these institutions for their assistance in recording these tests.

I experimented with different preparations: One third and one per cent. T. P. from the Saranac laboratory; one per cent. T. P. from the New York Health Board Laboratory; one quarter, one half, and one per cent. solutions of Parke, Davis Co. compressed tablets of T. P.; one per cent. and five per cent. dilutions of T. O. from the Alexander laboratories, Marietta, Pa. My observations are therefore not uniform and do not permit of statistical tabulation.

The results of most observers are favorable to the method. The application of the test in cattle has been very satisfactory and confirmed by the hypormic test.

My general impressions are: The conjunctival test has fulfilled all reasonable expectations. It is best with apparent discrepancies which we are yet unable to explain. It opens up many new and interesting questions. It will, of course, never take the place of a careful physical examination. It requires caution in its application and interpretation. It should be used judiciously so as not to bring it into discredit. It is important that we try to follow up our cases so that we ultimately get an insight into the causes of the failures of the method.

In conclusion, I shall unote the method of procedure, suggested by Dr. Baldwin, of Saranac Lake Sanatorium, for the diagnostic application of tuberculin: We should agree to use, say, simultaneous scarifications of ten per cent. and twenty-five per

cent, old tuberculin as the first test. If a reaction occurs to the ten per cent, use 0.5 per cent, in the eye for confirmation, except in children, within fortyeight hours, repeating in the other eye with two per cent, if desired in case of no reaction. Should a reaction occur only to the twenty-five per cent. skin test, confirm by one per cent. or two per cent. in the eye on the basis of Wolff-Eisner's findings that only sixteen per cent, of clinically nontuberculous persons react to the conjunctival test. If no reaction occurs to the skin test, omit the conjunctival test and proceed to the subcutaneous test if thought desirable. This scheme contemplates the abandonment of the subcutaneous test when reactions occur in the skin or eye, and both the conjunctival and subcutaneous test for children, because practically all the positive reactions in the skin and eye have been confirmed when controlled by the subcutaneous test. This procedure commends itself by its conservatism and

60 East Fifty-eighth Street.

THE CALMETTE REACTION AS A DIAGNOSTIC

AID.

By Clarence P. Oberndorf, M. D.,

New York,

House Physician, Bellevue Hospital.

Since the introduction of the Calmette ophthalmic reaction about a year ago, opinion as to its value has been so varied that its use has been limited largely to those collecting cases for statistical purposes. Recently it has been flatly condemned by many leaders of medicine and abandoned after a fleeting trial. Inasmuch as it is not used at all in many large hospitals, the results of its employment, as a diagnostic aid purely, may prove of interest.

All the cases, eighty-three in number, were in the general medical service of Dr. W. Gilman Thompson, of Bellevue Hospital. Among the class of patients treated at Bellevue, or in any similar rapidly changing, cosmopolitan, charity service, definite and speedy diagnosis for purposes of segregation of the tuberculous is essential. Moreover, in such a service, history taking is extremely difficult. The value of reliable histories in suspected tuberculosis cannot be overestimated, but among the ignorant English speaking patients the yea or nay is dependent upon the internes' attitude and inclination. Among the foreign born of naturally inferior intellect, an attempt at intelligent consideration of answers translated by an untrustworthy interpreter is almost impossible. Here every additional aid to diagnosis is welcome.

Method of instillation.—The method of administration of the eye tuberculin is, I think, original. Instead of dropping the solution into the eye with a pipette or minim dropper, a platinum loop, about two millimetres in diameter, is used. The loop is sterilized in a flame, a loopful of the tuberculin solution taken from the bottle and gently touched to the inner canthus of the eye. The advantages of this procedure are the facility of sterilizing the loop over the minim dropper, the certainty that the tuberculin reached the canthus, and the small amount necessary to be used. The quantity, less than one

¹ c. . I takerour wash countrat be offered for all in

To Dr. Thompson I am indebted for the privilege of reporting

quarter of a minim of the three per cent. crude tuberculin solution supplied by the New York Board of Health, seems to be all that is necessary

for a distinctive reaction.

To this method we attribute the absence of violent reactions which have been so often recorded. There were but three cases of conjunctivitis sufficiently severe to require treatment. Curiously enough, all of these occurred in cases in which there was considerable doubt as to the tuberculous diagnosis. They all subsided promptly under ordinary cold boric acid compresses.

. The test was not employed in every or any case with the object of running up statistical evidence. It was tried probably in less than six per cent. of the total admissions to the service. But where tuberculosis appeared to be a factor in the disease picture, a test was ordered as routinely as a Widal might be tried in suspected typhoid or a needle inserted on sufficient signs of pleural effusion. However, where there was evidence of conjunctivitis, panus, or only one sound eye, the test was omitted, even though, in many instances, it might have proved of value.

The tuberculin used was a three per cent. solution of crude tuberculin supplied by the New York Board of Health. It keeps excellently without diminution in its potency for at least two months if stored in an ice box. Should the question of the potency of tuberculin arise, as occurred on two occasions after a series of consecutive negative reactions, it may be tested in hospital practice by instilling into the other eye of a patient who has previously given a positive result. The size of a loop and its corresponding content, within a millimetre, is immaterial, provided that the quantity is less than half a minim.

In this series of cases the judgment, where there was any question of reaction, was recorded as decided by the five members who constitute the house staff. In those few instances where there was a difference of opinion, the reaction was repeated in the other eye. It might also be added that the tests were all recorded immediately after instillation, as was other evidence for or against tuberculosis which appeared subsequently. In this manner the judgment of the reaction was not influenced by other tests. Almost all of the installations were made in the evening, inasmuch as experience soon showed that where the reaction was so slight as to disappear entirely in twelve hours it might be disregarded.

SUMMARY.

* indicates that case does not quite correspond with the reaction.

I. Suspected apical tuberculosis, 19. Negative, 8. Temperature negative in all cases. Signs considered indefinite in all cases. Positive, 11. Temperature corroboratory. Signs definite, 10 cases. *Considered clinically doubtful, I case.

II. Pulmonary tuberculosis advanced, 4. *Negative, 2. Signs and temperature typical tuberculous, I; signs good, temperature flat, I; no bacilli in fæces or sputum, 2. Positive, 2. Signs and temperature tuberculous, 2; bacilli found, 1.

III. Distinctive between tuberculosis and pneumonia, 12. Negative, 9. Crisis or lysis in all cases. Signs cleared up in all cases. Positive, 3. Temperature tuberculous, no leucocytosis, all cases. Signs persisted, all cases.

IV. Bronchitis, 3. Negative, 1. Attacks asthmatic. Positive, 2. Temperature tuberculous, signs

persisted, 2.

V. Distinctive between unresolved pneumonia and tuberculosis, 1. Negative, 1. Signs disap-

peared, temperature corroboratory.

VI. Pleurisy with effusion, 11. Negative, 8. No bacilli in chest fluid, 5; temperature flat, 5; temperature septic, pus found, 2; *tubercle bacilli in chest fluid, 1. Positive, 3. Bacilli in chest fluid, 1; long continued tuberculous temperature, 3.

VII. Pleurisy, fibrinous, 3. Negative, 1. Temperature flat, chest emphysematous. Positive, 2. Temperature and history corroboratory, 2.

VIII. Bronchiectasis,* 1. Negative, 1. sputum examinations negative, temperature flat.

IX. Hydropneumothorax, 2. Positive, 2. Bacilli in sputum and chest fluid, 2.

X. Pyopneumothorax, 1. Positive, 1. Temperature and history tuberculous. Pus sterile.

XI. Hæmatemesis, 1. Positive, 1. Temperature flat, no signs. Bacilli found in sputum. Von Pirquet's test positive.

XII. Hamoptysis, 1. Positive, 1. No signs,

temperature flat, bacilli found.

XIII. Enterorrhagia, 1. Negative, 1. Temperature flat, attributed to cirrhosis.

XIV. Chronic diarrhaa, 1. Negative, 1.

tubercle bacilli in fæces.

XV. Cystitis, 2. Negative, 1. No bacilli found in urine. History gonorrhœal. Positive, 1. Bacilli found in urine.

XVI. Irregular, unexplained fever, 6. Negative, 4. Sepsis unexplained, 2; typhoid, 1; salpingitis, I; septic cases ran high leucocyte count. Positive, 2. *Staphylococcus pyogenes aureus septicæmia, I, focus not found. *Temperature typically tuberculous, I; focus not found.

XVII. Adenitis, unexplained, 5. Negative, 2. Temperature flat, 1. Disappeared under mercury, 1. Positive, 3. Lymphatic leuchæmia bacilli in sputum, 1. Glands almost suppurating, 1. *Possible doubt as to nature of glands, I. Chest fluid showed high lymphocyte count.

XVIII. Arthritis, 2. Positive, 1. Tuberculous hip at autopsy. Negative, 1. Gonorrhœal history

XIX. Controls, 5. Negative, 5. Chronic cardiac valvular disease, 1; morphinism, 1; subacute rheumatic fever, 1; myelitis, 1; exophthalmic goître, 1.

It will be seen that of the eighty-three reactions recorded, thirty-seven were positive and forty-six negative, and that, in the main, the reaction seems to correspond very favorably with the clinical inter-pretation of the case. There was one flagrant contradictory example among the negative results-the only instance in which the bacilli were found, thus affording definite proof in opposition to the eye test. This was in a boy of nineteen, where pleurisy with effusion developed in conjunction with an acute rheumatic fever and a chronic endocarditis, complicated by an acute pericarditis. The Bellevue Hospital pathological laboratory reported tubercle bacilli in the pleural effusion. The boy left the hos-

pital cured after an illness of two months, and remained in good health, when seen two months after his discharge. Unfortunately, no second test in the other eye was made, as it frequently happens that the first test, owing to the fact that the tuberculin

does not reach the canthus, is negative, while a second test proves positive.

The negative reactions in cases of advanced tuberculosis seem to coincide with the general consensus, that very advanced patients often fail to react.

However, in neither of these patients did examination of the sputum or fæces reveal tubercle bacilli.

Among the positive reactions, one case, an anæmic effeminate youth with vague signs at the right apex, gave a positive result. He entered the

hospital with marked hæmaturia, a high temperature, and complaining of general weakness. No bacilli were found in the sputum or urine. His temperature dropped after four days, and he left the hospital.

Two patients with fever, one with a Staphylococcus pyogenes aureus septicæmia and the other, an atropic cirrhosis of the liver with ascites, running a temperature with an evening rise and morning drop for over a month, reacted positively, when no tuber-culous focus was discovered. In both cases the sputum was negative, and in the Pyogenes aureus case examination of the prostatic fluid—the prostate being large and tender-revealed no bacilli. In neither of these patients could we discover any affirmative symptom or distinct sign of tuberculosis. The patient with septicæmia, however, recovered under the vaccine treatment, and later reacted to two milligrammes of tuberculin injected hypoder-The reaction was accompanied by the matically. return of the ocular inflammation, although the Calmette test had been tried one month previously.

On the other hand, in many cases where the evidence of tuberculosis seemed disparagingly slight, the positive eye reaction called prompt attention to an important factor in the case-in some instances to the only demonstrable cause of the patient's malady. In one instance, a patient with marked signs of exophthalmic goitre entered the hospital with symptoms which pointed to an old fracture of the hip. Her history varied from day to day, so that it was more confusing than valuable. She was first admitted to a medical ward as a case of chronic rheumatism, then transferred to the surgical side as an old fracture of the hip. A fracture of the hip was ruled out by the surgeons, who thought the case a neuropathic joint. Gonococci being found in the vaginal smear, she was presented to students at a clinic as a possible gonorrheal hip. The eye test finally clinched the diagnosis of tuberculosis of the hip, which had been considered from the start, and which autopsy proved to be correct.

On the negative side, cases might be cited equally convincing—e. g., a man who had been treated for pulmonary tuberculosis in a hospital for tuberculosis for three months without definite signs in his chest, gave a negative eye reaction, repeated negative sputum examinations, failed to react to three milligrammes of tuberculin injected hypodermically,

and ran a flat temperature.

In conclusion the negative reaction may, as a rule, be considered very strong proof that the patient has not tuberculosis, unless there be most important evidence clinically to the contrary. I might mention here, that by accident a twenty-five per cent glycerin emulsion of Koch's old tuberculin, intended only for the skin reaction, was instilled into the eye of a girl of fourteen without the slightest effect. The case eventually turned out to be one of typhoid.

Positive reactions warrant a lengthy and most minute search for some tuberculous focus. It may be impossible to discover it, and therefore it may be necessary to neglect the reaction, but in very many cases the positive reaction, even in the least expected instances, will be later affirmed by indisputa-

ble evidence of tuberculosis.

While the Calmette test is not infallible, we have found it, instilled in the manner described, entirely harmless and fully on a par so far as reliability is concerned with throat cultures in suspected diphtheria, Widal's in suspected typhoid, or the frequently disconcerting leucocyte counts in obscure

febrile cases. More accurate usually than the fallible ear and percussion finger, simpler by far than hypodermatic tuberculin reaction, negatively far more satisfactory than a negative sputum, fæces or urine report, the ophthalmic tuberculin reaction, sanely employed, may, within broad limits in hospital routine, exclude a diagnosis, confirm a diagnosis, or furnish a clue which cannot be allowed to pass unconsidered and unchecked.

THE TUBERCULOOPHTHALMIC REACTION. Report of Five Hundred Observations.*

By Frank L. Christian, M. D., Elmira, N. Y.

In May, 1907, Wolff-Eisner and Chalmette announced a new diagnostic test for tuberculosis Since then other investigators have conducted many thousand tests. Considerable doubt has been cast upon the accuracy of the procedure, and the results do not, in all respects, seem to bear out the contentions of the discoverers.

It is not my intention to review the mass of recent literature, but simply to report the result of my observations in making this test upon five hundred

individuals.

The test is made by instilling a one per cent. sterile solution of tuberculin into the eye. Care should be taken to insure cleanliness, as a traumatic

conjunctivitis is easily produced.

The tuberculin is furnished by the laboratories in tablets, powder, or in suspension in sterile glass tubes. In conducting these tests the tablets were used. One tablet is dissolved in five minims of sterile salt solution, and one drop is carefully instilled into the eye. The lids should be held apart for a minute or more to allow equal distribution of the fluid and to prevent the patient from rubbing the eye. It is well to note the exact condition of

the conjunctiva before making the test.

It is asserted that if tuberculosis exists an inflammation of the conjunctiva will occur. This reaction usually is noticeable in from four to forty-eight hours. In the majority of the patients the conjunctivitis was apparent in from eight to fifteen hours. In but two instances was it delayed longer than twenty-four hours. Usually there was some slight itching, lachrymation, redness, and swelling of the caruncle; in others some very evident conjunctivitis. A very few had a severe conjunctivitis, that yielded readily to simple treatment in a day or two. In many the reaction was very slight and fleeting, and most careful observation was necessary to determine the result. This mild form may to some extent account for the discrepancies found in the reports of various observers.

No permanent damage was done in any case. There was no febrile reaction or systemic disturb-

ance of any character.

A thorough examination of the eye is essential in every instance, for a severe and perhaps dangerous reaction would undoubtedly occur if tuberculous lesions were present in the eye.

There is apparently no relation between the intensity of the reaction and the severity of the lesion.

^{*}Read at the annual meeting of the Keuka Lake Medical and Surgical Association.

This is well illustrated by the absence of the reaction in moribund cases. Some of the most severe reactions encountered were in beginning tuberculous cervical adenitis. The reaction is present regardless of the location of the tuberculous process.

One hundred normal individuals were selected, and in no instance was a positive result found upon the first installation. These cases were all very carefully chosen, and only those individuals known to be and to have been in excellent health were tested. It was observed, however, that if any healthy individual was subjected to frequent tests a positive reaction could be obtained. This is no doubt due to an increasing hypersensitiveness of the conjunctiva. In this connection it is well to remember that the preparation used is not a true solution, but a watery suspension containing free particles. Unless care is taken to secure complete separation of the tablet, traumatic conjunctivitis may result.

In testing the reaction in tuberculosis, two hundred and ten cases were available, and the follow-

ing results were obtained:

Pulmonary tuberculosis (moderately advanced), positive, 52; pulmonary tuberculosis (advanced and moribund cases), negative, II; incipient tuberculosis, positive, 116; incipient tuberculosis (T. B. present in sputum), negative, 2; old tuberculous synovitis of knee (ankylosis healed and well for six years), negative, 1; tuberculous peritonitis (operation six years ago, well since), negative, 1; tuberculous testicle, positive, 3; tuberculous testicle (post operative), positive, 1; tuberculous hip (old, but recently had exacerbation), positive, 1; subacute tuberculous synovitis (knee), positive, 1; tuberculous asthma, positive, 1; Pott's disease (old, healed many years), negative, I; active tuberculous osteomyletis (humerus), positive, 2; tuberculous cervical adenitis, positive, 12; tuberculous meningitis, positive, 3: chronic rheumatism, arthritis, and pulmonary tuberculosis, positive, 2.

Results: Positive, 194; negative, 16; total, 210. In all of the advanced and moribund patients the reaction was invariably negative. Excluding these as a recognized phenomena, the reaction was present in all but 2½ per cent. of the tuberculous

In the various forms of rheumatism the reaction is frequently positive. Pheln found it so in six out of twelve cases of acute articular rheumatism.

In this series in sixty cases of rheumatism (including one case of gonorrheal rheumatism), the reaction was present in thirty-six and absent in twenty-four, the cases being classified as follows:

Acute articular rheumatism and endocarditis, positive, 9; acute articular rheumatism and endocarditis, negative, 4; subacute articular rheumatism, positive, 26; subacute articular rheumatism, negative, 20; gonorrheal rheumatism, positive, 1. Total, 60.

Owing to the result obtained in these reactions, a further test was made in six cases of subacute articular rheumatism. The ophthalmic test was repeated after a period of from six to ten days, and at the same time 0.001 milligramme of T. R. was administered subcutaneously. In two patients the ophthalmic test was positive, and there was also a

well marked febrile reaction to the injected tuberculin. The other four patients were absolutely negative to both reactions. Owing to the absence at this time of available cases of rheumatism, extended observation was impossible.

No satisfactory conclusions can be based upon these few cases, but the result affords thought upon the ætiology of rheumatism. It is quite probable that tuberculosis may complicate rheumatism or vice versa more often than we have been led to suspect.

In one hundred and ninety individuals ill from disease other than tuberculosis, the reaction was present forty-four times, thirty-six of these positive results being previously mentioned in rheumatic patients.

Out of seventeen cases of influenza five gave a positive reaction. There was no clinical or microscopical evidence of tuberculosis in any of these five and has not been up to the present time. In three instances in which the pleura alone was involved a positive reaction occurred. These patients could no doubt be well included among the tuberculous subjects, many authorities maintaining that most pleurisies are of tuberculous origin.

The following is a list of the medical cases which were subjected to this test and the result obtained, the tuberculous and rheumatic cases being excluded:

| | Number test -1 |
|--|----------------|
| Asthma | Negative 4 |
| Morphinism | Negative 1 |
| Epilepsy | .Negative 6 |
| Enteritis | . Negative : |
| Influenza | . Negative 12 |
| Influenza | .Positive 5 |
| Anæmia, (simple) | .Negative 6 |
| Mitral regurgitation | . Negative 5 |
| Mitral stenosis | Negative I |
| Lobar pneumonia Parotitis Acute bronchitis | . Negative / |
| Parotitis | . Negative 4 |
| Acute bronchitis | . Negative T |
| rieurisy with effusion | . Positive > |
| Old plastic pleurisy | .Positive 1 |
| | |
| Total | 5% |
| | |

Forty-six nontuberculous surgical cases were observed, and in no instance was there a positive reaction. The following is the result:

| Number to | |
|--|-----|
| and resu | lt. |
| Cervical abscess | E |
| Puritus ani Vegetive | |
| Puritus ani Negrtive Gunshot wound of leg. Negative | ī |
| Damorrhoids Vegative | |
| Suppurating testicle (traumatic)Negative | T |
| Erysipelas | |
| Tonsillar abscess | 3 |
| Rectal prolapse | I |
| Ubstructive icterus Vegative | |
| Filtillosis (Dostoperative) | 4 |
| Cantillas (streptogrecie) | - |
| incised and lacerated wounds Negative | 3 |
| varicocele (postoperative) | T |
| Phlebitis Negative Angeiosarcoma Negative Mastoicitis Negative | |
| Angeiosarcoma | |
| Mastoiditis Negative | |
| I faumatic confunctivitis Negative | I |
| Dating of feet and feet the feet free feet free | 1 |
| Various fractures Negative | 4 |
| Acute office media Nagativa | ī |
| Acute gonorrhœal epididymitisNegative | 3 |
| | |
| Total | |

It is interesting to observe that while one patient with gonorrhoeal rheumatism gave a positive result, three patients with acute gonorrhoeal epididymitis were all negative. Other observers have reported positive results in gonorrhoeal rheumatism.

The usual infections accompanying erysipelas, cellulitis, and mastoiditis might well have been expected to give a positive reaction, as did the systemic infection in so many cases of rheumatism;

this, however, did not occur.

Some investigators have reported positive results in syphilis, but in this series all were negative, as shown by the following data concerning twentyeight dermatological patients:

| | and Result. |
|--------------------|-------------|
| Primary syphilis | Negative 8 |
| Secondary syphilis | Negative 11 |
| Tertiary syphilis | Negative 7 |
| Scabies | Negative 1 |
| Psoriasis | Negative I |
| 77 | -0 |
| . Total | 28 |

Conclusion.—The test is rapid, simple, and convenient. If necessary to repeat it should not be applied to the same eye. A positive reaction may follow frequent installations in a normal individual. The test should not be applied to any but a normal eye; serious results may follow instillations into a diseased eye. The reaction is of value in the diagnosis of early tuberculous lesions. The reaction is negative in the advanced lesions of tuberculosis. The reaction alone cannot be held to be conclusive, still in the presence of other signs it furnishes confirmatory evidence of much importance. The reaction occurs in conditions other than tuberculosis, and must still remain secondary to a careful physical examination.

NEW YORK STATE REFORMATORY.

PRELIMINARY REPORT ON THE EFFECT OF REPEATED INJECTIONS OF TUBERCULIN ON LYMPHATIC ORGANS.

By Samuel G. Dixon, M. D., Allen J. Smith, M. D., and Herbert Fox, M. D.,

Department of Health of the Commonwealth of Pennsylvania (Medical Laboratories, University of Pennsylvania).

The condition of the spleen in guinea pigs after treatment with tuberculin on some product of the tubercle bacillus like it, suggested that this organ might be the seat of some pathological change after injections of these solutions. The question naturally arose whether the inexplicable deaths among cattle after testing might not in some way be connected with this substance. In the course of our work in this laboratory, we have repeatedly encountered focal necroses in the spleen, and occasionally in the liver of guinea pigs and rabbits dying of the injections of the various tuberculins. These necroses were suggested by the naked eye appearance. The lymph nodes were not attacked by these areas, even those in close proximity to the point of inoculation. The foci of necroses were not sharply outlined but usually were surrounded by large lymph cells or endothelium. Around the older ones was sometimes a zone of polynuclear, and round cells, rather indicating a throwing off of the necrotic remains. The endothelium is almost always slightly hyperplastic. In order to see if severe treatment of a healthy cow with tuberculin would produce anything similar to this an animal was injected six times, two weeks apart, with 400 milligrammes of old tuberculin under the skin. She did not react at any time. She was killed two weeks after the last dose and at autopsy appeared to the naked eye to be a healthy animal. The pathological histology of spleen, lymph glands, and liver is as follows:

Lymph nodes: In none of a number of sections were there noted any areas of necrosis of focal development, suggesting tubercles. The glands are in some instances more or less hyperæmic. In all, the follicles and chords seem large. Many of the follicles show large endothelial germinal centres; and in the sinuses there is considerable endothelial swelling and hyperplasia. In other words, the notable features are a combined lymphoid and endothelial hyperplasia. To this may be added in some of the sections, in the medullary parts of the nodes a slight cedema of the connective tissue and a slight scattered polynuclear leucocytic and eosinophilic infiltration, and a minor grade of hæmic pigmentation. Compared with the normal glands, there is perhaps a slight increase in the amount of endothelial cell proliferation; this is not very marked.

Spleen: There is not so much fibrosis in this organ as in that of the healthy control animal; and there is a decidedly larger size of the Malpighian bodies, which generally show central endothelial proliferation of marked grade. Some of the centres of endothelial hyperplasia show moderate necroses with swelling, vacuolization, and loss of nuclei. The endothelium in the spaces may also be seen to be necrotic, occasionally phagocyting or pigmented. There is a slight excess of polynuclear leucocytes in the pulp; and the endothelium of the pulp is quite prominent. Here and there small multinucleated cells of endotheliod type occur, not, however, suggestive of the type of tuberculous giant cells.

Liver: Shows practically no changes beyond a fine vacuolation of the cells, which is, however, unaccompanied by any staining fault of the nuclei or cytoplasm. There is a slight excess of small mononuclear cells in a few small areas, not in definite nodes but scattered along some parts of the interlobular connective tissue and along some of the intralobular capillaries. The capsules of Glisson are not increased for bovine livers, although the tissue

about the bile ducts is quite marked.

As a control, tissues were taken from an apparently normal healthy cow killed at the abattoir; they include material from the compound lymph glands and spleen. From the history which could be obtained of this cow, she had not received tuberculin lately. Neither is, however, normal. There is excess of fibrous tissues, notably in the splenic trabeculæ and pulp, but also involving the lymph nodes; and in both there is both follicular and more or less diffuse endothelial hyperplasia; in both more or less well marked congestion and in the spleen a slight grade of hæmic pigmentation. None of the centres of endothelial hyperplasia show any necrosis nor is there any phagocytosis.

This demonstrated that the prescribed treatment

of this cow did not produce any distinct focal necroses. There was, however, a tendency for hyperplasia of the endothelium which went on to vacuolization and necrosis. This was more diffuse than usually seen in guinea pigs' spleen and affected frequently the sinus and endothelium.

Although the endothelium has suffered in both the guinea pigs and the cow, no hæmorrhages were present either great or small, thus speaking against any lytic change. The phagocytosis and pigmentation rather lead us to attribute the degeneration to

great proliferation incident to the toxemia.

Our Renders' Discussions.

A SERIES OF PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

LXXVII.—How do you treat varicose ulcer? Closed

August 15, 1908.)

LXXVIII.—How do you treat acute coryca? (Answers due not later than September 15, 1908.)

LXXIX.-How do you treat sick headache? (Answers

LXXIX.—How ao you treat sice neaduche: (Answers due not later than October 15, 1908.)

Whoever answers one of these questions in the manner most satisfactory to the editors and their advisers will receive a prize of \$82. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not REQUINED) that the answers be short; if practicable, no one answer to contain more than six hundred records. words.

All persons will be entitled to compete for the prize, whether subscribers or not. This prize will not be awarded whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Jounnal. The prize of \$25 for the best essay submitted in answer to question LXXVI has been awarded to Dr. Beverley Robinson, of New York, whose article appeared on page 407.

PRIZE QUESTION LXXVI.

THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

(Continued from page 411.)

Dr. Ottice N. Eisaman, of Pittsburgh, Pa., says:

Acute articular rheumatism, has to be distinguished from a few conditions which it resembles. But when we have heat, redness, pain, and swelling in two or more joints that occur, in order of frequency, in knee, ankle, shoulder, wrist, elbow, and hand, although any joint may be involved. In external cases the muscles near the joints become tender and rigid. There is sudden rise in temperature from 102° to 104° F., the temperature becoming irregular, possibly due to the profuse acid sweat. The patient complains of thirst and constipation; urine is scanty and loaded with urates, and often contains albumin. The pulse is rapid, usually above 100, and soft. Anamia is common, and we find a marked leuco The duration of an attack varies from a cytosis. few days to six or more weeks.

I order my patient to bed between woolen blankets, with woolen night shirt open in front, sleeves slit so that the infected joints can be locally treated. The room should be well ventilated, temperature 75° F. A saline cathartic should be given in the

beginning, and the movements of the bowels carefully noticed throughout the course of attack. Fixation of the joints involved is essential, and can be done by plaster of Paris splint, or by light boards well padded with cotton. The joints must be wrapped with woolen bandages, and over this should be placed a piece of oiled silk before applying the splints. Solution of sodium bicarbonate, 20 grains to the ounce, is used to keep the bandages around joints moistened, applied warm every two hours, by separating the oiled silk, or by using Fuller's solution, whose formula is sodium bicarbonate, 6 drachms; laudanum, 1 ounce; glycerin, 2 ounces; and water, 9 ounces. Larger amounts of laudanum can be used in Fuller's lotion. The best of the internal treatment is probably salicylates in form of sodium salicylate, 20 grains, every two hours, in simple elixir. The simple elixir prevents irritation of the stomach. When the pains are extreme, and the patient cannot get rest, morphine sulphate, hypodermically, must be resorted to, which tends to also prevent cardiac complications. Careful attention must be paid to the heart, and if no pathological conditions are found at first examination, note it, as soon as they appear. Cardiac complications are most dangerous, which occur in order of their frequency, endocarditis, pericarditis, and myocar-When treatment for these conditions is called for, the ice cap applied over the cardiac region, or a series of small blisters in the same region over intercostal spaces from third to sixth rib, proves beneficial. As pain disappears and the temperature becomes normal, the salicylates should be gradually withdrawn.

As to diet, milk is the ideal food, given diluted with mineral waters. If milk cannot be borne, soups and broths flavored with vegetable extracts, or chicken, tea, milk toast, and oat meal can be substituted. Lemonade is allowed. As long as there is elevation of temperature, liquid or semiliquid foods are used in order to carry on proper elimination. Alcohol is allowed only where anæmia is marked, in tonic doses. Diluted whiskey is probably the best form. The patient must be kept in bed some time after temperature has become normal and pain has disappeared, the time left to the judgment of the physician. During convalescence iron is given in form of elixir of iron, quinine, and strychnine, one drachm every four hours. As the appetite returns the diet must be carefully watched. Farinaceous and not saccharine foods must be selected. oat meal, milk toast, unsweetened puddings, wine jelly, and malted foods are suitable. Eggs and white meats are gradually added to the list, before ordinary meats. Meats given too early may induce relapse. Careful instruction should be given to the patient in order to avoid recurring attacks.

Dr. C. W. Gillette, of Schuylkill Haven, Pa., states:

The treatment of a case of acute articular rheumatism resolves itself into making the patient comfortable, to relieve him of the annoying symptoms, to protect the heart, and to cure the disease.

The patient should be kept in bed, upon a soft, firm mattress, with springs that do not sag. room should be well lighted and well ventilated, with care that no draughts come in contact with the patient. In cold weather a woolen or canton flannel night dress should be worn. In hot weather light coverings are sufficient. A tepid sponge bath should be given every morning under covers.

The swollen and painful joints should be wrapped with cotton, saturated with lead water and laudanum, or with Fuller's lotion, and kept applied for forty-eight or seventy-two hours, if the skin is unbroken. In addition, fixation of the joint with moderate flexion, if at knee or elbow, should be made upon a well padded splint. All manipulation of the affected joints should be guarded against during the acuteness of disease.

For the restlessness, pain, and insomnia morphine is usually indicated in severe cases. It quiets the restlessness, relieves the pain, promotes sleep, and does not depress the heart. The sulphate, ½ to ¼ grain, should be given subcutaneously, combined with atropine sulphate, 1/150 grain, when sweating is excessive. Usually, with proper treatment, an evening dose continued for three days to a week is sufficient. Care should be exercised in

continuing its longer use.

Protection of the heart is best accomplished by absolute rest in bed. The urinal and bed pan should be used in severe cases. The diet should consist of milk, 4 to 6 ounces every three hours. If milk is not well borne, it should be peptonized, or buttermilk, broths, and light soups may be substituted.

The internal medication should be started with small doses of calomel. In sthenic cases, with high fever and rapid bounding pulse, give of the following a teaspoonful in wine glass of water ev-

ery hour:

| \mathbf{R} | Tinct. of aconite, | , |
|--------------|---------------------------|---|
| | Sweet spirit of nitre, | |
| | Potass. citrate, | |
| | Water,enough to make 3iv. | |
| M. | | |

If hyperpyrexia is present, cold sponge baths are indicated.

After the bowels have been freely moved and the system impregnated with the cardiac sedatives, usually within twelve to twenty-four hours, discontinue this prescription and give 10 grains sodium salicylate every hour for five or six doses, repeating doses again on second and third day if no untoward symptoms arise. The dose should then be reduced to 5 grains, three times daily, for it is useless to further push the drug if no good has re-In conjunction with the salicylate, give potassium citrate. 15 grains, in a wine glass of water every three hours. During the administration of the salicylate the heart should be carefully watched, as the drug in large doses tends to weaken the heart muscle. The urine should be examined daily for albumin and casts, and upon any untoward effects on either of these organs or the stomach their administration should be discontinued. If the stomach is irritable the salicylates may be tried by rectum, or an ointment of salicylic acid, 11/2 drachms; oil of turpentine, 30 minims; lanolin, 1 ounce; one drachm to be rubbed into the affected joints daily.

For the anorexia and coated tongue keep the bowels acting daily and give the following in wa-

ter after nourishment:

| Γ_k | Finet, of nux yomica, | |
|------------|-----------------------|----------|
| | Extr. of gentian, | . m is : |
| 3.4 | Essence of pepsin, | 51. |

Anæmic patients give cod liver oil and syrup of iodide and iron after acute symptoms subside.

In cardiac complications place an ice bag over the præcordial region, followed by small blisters, keep patient on back, and administer morphine if pain is severe. In cases that hang on, give potassium iodide, 5 to 10 grains in a drachm of comp. syrup of sarsaparilla, three times daily after meals. Stiffness of joints are to be treated with massage and steam baths.

In conclusion, if the salicylates or other drugs disorder the stomach, stop their administration for a time, at least, and give the stomach a rest and Nature a chance. With careful nursing, milk diet. plenty of water to drink, and the external treatment described, many patients will improve.

Dr. Joseph Di Rocco, of New York, observes:

In treating this disease there are certain factors which we must bear in mind, namely: I, We have to deal with an acute infectious disease, causing arthritic manifestations. 2. That in salicylic acid or any derivatives of such we have a so called specific drug to combat the rheumatic poison. And with the latter point in view we must get the patient as quickly as possible under the influence of the drug; and then to increase the interval of administration and not the dose, and finally to continue in decreasing doses for a long time.

In the prophylaxis several points are noted, especially for those who have inherited certain tendencies towards the disease, and for those who have had the disease: 1, Sufferers should avoid exposure: cold, and wet, and overfatigue; 2, should, wear flannels all year, light ones in the summer: 3, should take exercise, fresh air, and keep the skin in good condition by frequent bathing; and, 4, should avoid indiscretions in diet and drinking.

During an attack put the patient to bed, in a well ventilated room, and keep him absolutely quiet, for it is very hard to say whether he shall be there for one week or for six weeks. Diet is exclusively milk at the start, to which may be added vichy; but later on, when the rheumatic symptoms have disappeared, we can give soups, plain broths, crackers, toast, farinaceous foods. Medicinally, after giving our initial dose of 5 grains of calomel, with 15 grains of sodium bicarbonate, to be followed in four to five hours by 2 ounces of Rochelle salt, we fall back upon our specific drug. Perhaps the best way in administering this drug is thus:

| $\mathbf{P}_{\!\scriptscriptstyle{F}}$ | Acid. salicylici, | | | | | | | | | | | | | .3v | iiss | |
|--|-------------------|----|--|-------|--|------|--|--|------|-------|------|---|---|------|------|---|
| | Sod. bicarb, | | | | | | | | | | | | | | | |
| 3.5 | Aquæ gaultheri | æ, | | ٠ | | | | | | ٠ | | ٠ | - | | . 51 | L |

Sig.: One teaspoonful every three hours in plenty of water.

Once in a while we have to deal with patients who cannot stand the salicylates; persons who have idiosyncrasies towards the drug, as shown by severe vertigo, nausea and vomiting, ringing in ears, heart palpitation, and perhaps nose bleed, then we may give any one of the following: Oleum gaultheriæ,

 $M \cdot x$, in capsules, every three hours; or aspirin, grain v, every four hours; or salicin, grain x, ev-

ery three hours.

For the relief of special symptoms such as pain and fever, we note that in most cases the treatment will help very materially in stopping the pain, and we should never be tempted to give coal tar products for the relief of pain. The fever in the majority of cases is not an element, but we may have a condition of hyperpyrexia in the rheumatic state, the temperature reaching perhaps 104° to 106° F. Then again do not be tempted to give any coal tar products to reduce such, but combat the condition with cold sponging.

with cold sponging.

The local treatment of the joints involved is not of so much importance, but if we keep in mind these three facts: I, To keep the joints immovable; 2, to protect them from injury; and, 3, to keep them warm, we have done all we can for them, whether we apply any local medication or not. The local drug medications are, I think, purely psychic in their effect; but the great importance is to give to the part involved absolute rest and keep it warm. We may use a fifty per cent. ichthyol salve, or oil of wintergreen and olive oil, or an alkaline solution,

 Tr. opii,
 .5i

 Glycerin,
 .5ii

 Aquæ,
 .q. s. ad. 3x.

 M

Sig.: Apply hot to the joints.

In this disease the treatment of the convalescent state is exceedingly important. It is much safer to keep the patient in bed about ten days after the subsidence of fever and joint symptoms; change the diet only after such subsidence, when we can add eggs, broths, vegetables, fish; game and meat only when the temperature has been normal for one week.

And, finally, to counteract the anæmia we give cod liver oil or some form of iron.

(To be concluded.)

Correspondence.

LETTER FROM TORONTO.

The American Public Health Association.—A New Section.

TORONTO, August 31, 1908.

The thirty-sixth annual meeting of the American Public Health Association was held in Winnipeg, Canada, on the 24th, 25th, 26th, and 27th of August, under the presidency of Dr. Richard H. Lewis, of Raleigh, N. C. The committee in charge of the arrangements of the meeting consisted of Dr. R. M. Simpson, of Winnipeg (chairman), who is also chairman of the Manitoba Board of Health; Dr. Gordon Bell, of Winnipeg; Dr. J. M. Eaton, of Carberry, Man.; Dr. F. L. Schaffner, M. P., of Biossevain, Man.; Dr. H. H. Chown, of Winnipeg; Dr. R. S. Thornton, M. P. P., of Deloraine, Man.; Dr. B. J. McConnell, of Morden, Man.; Dr. A. J. Douglas, M. H. O., of Winnipeg; Dr. J. A. Macdonald, of Brandon, Man.; Dr. James Patterson, of Milroy; Dr. Bodn, of Winnipeg; and Mr. E. M.

Wood, secretary of the Board of Health of Manitoba. Seventy-three new members were added tothe roll. Ten registered from Mexico. The official welcome on behalf of the province of Manitoba was delivered by the Hon. R. P. Roblin, Premier of Manitoba, and Mayor Ashdown offered greetings on behalf of the city. In his annual address the president referred to the recent call of the President of the United States for a conference at the White House on the vital question of the conservation of the country's natural resources, and stated that he had attended that important conference as the representative of the association. He recommended that the American Public Health Association take similar action to that of other national bodies in appointing a special committee to act with the President's commission in that respect. Referring to the matter of a national bureau of public health and the kind of bureau wanted, he said that the kind most desired was one which would include within its scope and management all the specific health agencies of the government now in existence. He considered that the most efficient teacher of hygiene to the people was the family physician, but he was generally found very indifferent. He illustrated the line which education of the people in sanitary matters should take by referring to a supposed outbreak of diphtheria. As soon as the secretary of the State Board of Health was notified he could telegraph to the head of the national bureau. From that source the people could then be immediately supplied with the authoritative information on the subject. The people should also be instructed by a corps of lecturers sent through the country. The president considered that the wisest way to pursue in obtaining the national bureau of health medical men desired to see in the United States, as well as in Canada, was to positively endorse the Public Health and Marine Hospital Service, advocating its further enlargement and the transfer of such health agencies from other departments as would legitimately come within the jurisdiction of such a

459

The afternoon session of the opening day was distinctly a Spanish one, two papers being delivered by Dr. Chico on smallpox. Dr. Elgin followed up these papers and gave his own experience in the matter of the effect of heat on vaccine lymph, and showed that in a range of temperatures from 65° to 15° C. the lymph's usefulness and reliability lasted from five minutes only at the higher temperature to four years at the lower. Dr. Evans, of Chicago, suggested this fact as a reason for the comparative failure of the vaccination of the troops in the Philippines, the lymph having twice crossed the ocean and having been subjected to an unusual degree of heat.

Dr. P. H. Bryce, chief medical officer of the Department of the Interior, Canada, contributed a paper on the Sociology of the Middle West. The paper opened with a reference to the farm acreage and value of the north central States from 1850 to 1900. Reference was made to the nationalities peopling these States; then the comparison was drawn with what Canada had done in the West in the past few years. The prophecy was made that the West in its progress would equal the States.

quoted. Dr. C. F. Fagan, of Victoria, B. C., medical health officer of the province of British Colum-

bia, read a paper on the same subject.

The report of the Committee on Ophthalmia Neonatorum was presented by Dr. F. Park Lewis, of Buffalo. It stated that a test made in ten schools, representing eight States and Ontario, showed that twenty-five per cent. of those first admitted to the schools were needlessly blind. The committee recommended that the public health officials should do everything possible to spread knowledge on the subject in general and its prophylactic and curative treatment; that all midwives should be examined and registered; and that proper records be kept in the maternity hospitals of the numbers of cases of ophthalmia.

The paper of Dr. Francisco De P. Bernaldez, of Mexico, on the Methods of Practising Vaccination with Human Lymph, was read in English by his colleague Dr. Chico. The paper recited the approved method in Mexico as adopted by the Vaccination Department of the Board of Health as follows: The region in which the vaccine is to be inserted is washed with sterilized water, soap, and a brush, the skin being rubbed until it becomes red, and then dried with sterilized cotton. The lancets are dipped in boiling water or passed through the flame of an alcohol lamp. The pustules are cleansed entirely with sterilized water and cotton. They are very superficially scarified and not used if they bleed. A small quantity of lymph is taken up on the lancet and the inoculation made in the person to be vaccinated by means of small punctures, almost joining each other and six to eight in number. The lancet leaves the lymph spread over the place where the punctures have been made. The punctures do not reach below the dermic layer of the skin. The object is to produce pustules in a series, making only one scar, numerous pustules, and painless vaccination. They can be easily examined to find whether they present the characteristics of true vaccination. Any other method leaves the operator in doubt as to whether the individual has obtained immunity or not.

The next interesting paper on the best method to practise vaccination was read by Dr. Miguel Merquez, of Chihuahua, Mexico. Like his colleagues he regarded puncture as a better method than scraping, and experiences gained in 30,000 vaccinations confirmed that. He considered that animal vaccine was safer than human, although in countries where there were no properly organized institutes for the culture of animal vaccine, the latter

could be used to good advantage,

Smallpox in Ontario was dealt with by Dr. James Roberts, M. H. O., of Hamilton, Ont. He spoke of an outbreak in Hamilton of eighty cases which had cost that city \$10,000. In nearly every case there had not been any vaccination at all, or at least none of recent character. Although in Ontario there were stringent laws compelling vaccination of all persons over three months old, the people were neglecting vaccination now as the ravages of small-pox were becoming less. He also considered that too many physicians were careless in establishing quarantine in mild cases. In discussing this, Dr. Evans, of Chicago, stated a committee should be

appointed to prepare a case against the arguments of the antivaccinationists and to secure the proper dissemination of such arguments.

A paper which attracted a good deal of attention and discussion was that by Dr. C. A. Hodgetts, secretary of the Ontario Board of Health. The title was Mortality Statistics of Canada during the Decade. That Canada was not a country for suicides was an interesting point brought out in the paper. He stated that the suicides of Canada for 5,000,000 of people only amounted to 147. One delegate considered this most remarkable, as he came from a city of 200,000 where the mortality from suicide was 112. The statement had considerable doubt thrown upon it, as in some provinces the collection of vital statistics is not proceeded with at

all, and in others only perfunctorily.

A new section in the work of the association was opened this year. It is constituted by municipal health officers. It had a programme of eight papers, as follows: The Rural Health Officer, by Dr. Charles A. Hodgetts, of Toronto; Protection of Public Milk Supplies, from Specimens Contaminated with Pus Organisms, by Professor J. O. Jordan, of Boston, Mass.; Problems of Quarantine in Contagious Diseases Work, by Dr. Francis George Curtis, of Newton, Mass.; Management of Infectious Diseases in Rural Municipalities, by Dr. L. M. Cleghorn, of Baldur, Man.; Approved Methods, the Chicago Health Department, by Dr. W. A. Evans, of Chicago; The Advantages of Publicity in Public Health Work, by Dr. Ernest C. Levy, of Richmond, Va.; Some of the Hopes and Pleasures of the Health Officer, by Dr. Charles V. Chapin, of Providence, R. J.; Disinfection of Rooms, by Mr. Bert R. Rickards, of Boston, Mass.

Dr. J. A. Amyot, bacteriologist of the Provincial Board of Health of Ontario, read a paper entitled Pollution of the Great Lakes and Rivers. These included an area of 98,640 square miles, and over 4,000,000 people were now using this source of water supply. The turbidity was generally not more than two parts to the gallon, except in Lake Erie, where it was from twenty to twenty-five parts. He made reference to the fact that Toronto had recently voted \$3,700,000 for the disposal of its sewage and the filtration of its Lake Ontario water, and was hoping for a big reduction in its typhoid and intestinal mortality. The conclusions drawn by most of the speakers was that this water supply of

the great lakes was perfect.

Dr. C. O. Probst, secretary of the association and also secretary of the State Board of Health of Ohio, advocated in a paper the control of the water supply by the State. Dr. Cressy L. Wilbur, chief statistician of the Bureau of the United States Census, Washington, read a paper in which he said that vital statistics were the Cinderella of modern public hygiene. She sat in the chimney corner and sifted the ashes of dusty figures while her proud sisters, Bacteriology and Medicine, went to the ball and talked about the wonderful things they had done. But the glass slipper fitted no other foot, and when we descended to facts and not mere empty bombast about the results of administrative work, we looked to vital statistics. What did we know about infant mortality, which all were so anxious to prevent,

when not a single State or city in the United States had the data for a correct statement? It depended upon the accurate registration of all births. What did we know about the facts of tuberculosis, while health officials acting as local registrars allowed deaths to be reported as "probably tuberculosis" and "possibly tuberculosis?"

Dr. J. N. Hurty, of Indianapolis, chairman of this section, deplored the fact that no State or province in North America at the present time col-

lected accurate statistics.

In his paper entitled The Purpose and Object of Morbidity Statistics and the Methods of Collecting Them, Dr. J. M. Eager, of Washington, pointed out that one method for improving the gathering of complete statistics was the payment of a fee. In those States where a fee was paid the returns were more complete.

Dr. Charles A. Hodgetts, of Toronto, secretary of the Ontario Board of Health, was elected presi-

dent of the association.

Therapentical Hotes.

Hyperæsthetic Rhinitis.--In the treatment of so called hay fever, a disease which, according to Sajous (Monthly Cyclopædia and Medical Bulletin for August, 1908) involves the internal secretions and to which he applies the more correct term, hyperæsthetic rhinitis, in view of the fact that the disease may be evoked by many irritants other than new hay, it is advised that attention should be paid to the pseudoform of the disease which is provoked in the presence in the nose or nasopharynx of polypi, exostoses, turbinal hypertrophies, etc. These projecting morbid tissues, mainly by irritating the sensory terminals of the surface opposed to them, render hyperæsthetic, not only this surface, but also the centre to which the sensory impulses are transmitted, that of the fifth nerve pair. Such cases are often not only sensitive to many pollens, but also to many commonplace irritants. They are readily cured, he asserts, by properly executed removal of the morbid growths, but in such a way that no adhesion or synechiæ are left between the opposed surfaces. Cauterization of the hyperæsthetic areas caused by them, by the local application of glacial acetic acid, chromic acid, or galvanocautery, tends further to insure recovery. In the number of the Monthly Cyclopædia and Medical Bulletin cited he instances cases of cures effected by caustic applications to the hyperæsthetic areas and describes the modus operandi of remedies administered internally, first showing how the morbid symptoms are awakened by the atmospheric irritants. When these specific irritants appear in the air, as interpreted from his standpoint, the violent sensory impulses transmitted to the trigeminal centre provoke reflex dilation of the arterioles which supply blood to the mucosa of the nose, sinuses, conjunctivæ, etc., and all these structures become intensely congested the exciting cause of the distressing symptoms. He therefore argues that beneficial effects can be obtained by remedies which either locally, or by acting on the sympathetic centre, provoke constriction of the dilated arterioles. He condemns the use of cocaine solutions, which, while effective, are dangerous owing to their liability to produce a cocaine habit in the patient. Far safer and just as efficient, according to him, is a weak-1 to 10,000-solution of adrenalin chloride, prepared with normal salt solution. This solution by depleting the engorged mucosa affords the patient considerable comfort, and this effect may be sustained by spraying over the constricted mucosa a solution of menthol in any light petrolatum oil, of the strength of five grains to the ounce. A saturated solution of quinine used as a spray, followed by the application of an oint ment composed of thirty grains of quinine and one ounce of petrolatum, are recommended by Fulton. These measures, however, should only be regarded as palliative, serving to relieve stenosis, allay irritability, and control excessive secretion.

As internal treatment belladonna has given Dr. Sajous the best results when used in conjunction with local treatment. To adults he gives 1/120 grain of atropine three times daily until slight dryness of the throat occurs, when the effect may be sustained by one or two doses daily. When asthma complicates the case he employs instead the follow-

ing preparation:

paroxysm is arrested.

Earlier in the article Sajous speaks of the gouty diathesis as being an underlying cause of hay fever, this diathesis being attributed to an inadequate breaking down of wastes. The only remedy which has served him faithfully in counteracting the gouty diathesis is desiccated thyreoid, which acts by enhancing, as do the iodides, the catabolism to toxic wastes. It may be given in two grain doses twice daily for three days, then once daily only. Strychnine in 1/50 grain doses after meals enhances the action of the thyreoid extract by stimulating the vasomotor centre and increasing the oxygen intake.

Medicinal Treatment of Acute Ecthyma.--In the belief that acute ecthyma is due to syphilis. Shoemaker (Monthly Cyclopædia and Medical Bulletin for August, 1908) gives the following com-bination of mercury and iodine to combat and arrest the disease:

Corrosive sublimate,gr. ii; hours after each meal.

He advises the following treatment of the ulcers: After the parts involved have been thoroughly cleansed with soap and water, the ulcers should be dressed with a I to 2,000 solution of corrosive sublimate, after which they may be dusted freely with a powder containing equal parts of calomel and boric acid. If they are resistant to this treatment it is recommended to cauterize them lightly with either pure carbolic acid or stick silver nitrate. These caustics are said to stimulate the ulcers to healthy granulation and bring about a rapid cure.

NEW YORK, SATURDAY, SEPTEMBER 5, 1908.

TUBERCULOUS DISEASE AND THE RED CROSS.

On June 29th the first tuberculosis day camp of the American National Red Cross was opened in Schenectady, under the auspices of the Schenectady County Subdivision of the New York State Branch of the Red Cross. It is the first of five Red Cross day camps established or to be established this summer in America. It is announced that a camp will be opened in Albany within a short time and another in New York on October 1st. Other Red Cross day camps have been established in Washington, D. C., and Wilmington, Del.

The Schenectady camp is situated in a pine grove on high flats in the southeastern part of the city. It has two permanent wooden buildings, an office and a kitchen, and on platforms a large dining tent, two hospital tents, one for men and the other for women, and two conical tents for night campers. A medical visiting committee, whose members visit the camp in turn for an hour or two a day, is composed of Dr. C. F. Clowe, Dr. H. L. Towne, Dr. Peter McPartlon, and Dr. J. H. Collins. The camp is in charge of a superintendent, Miss Sarah B. Palmer. who was in charge of the floating hospital in New York city for three years. The nurse is Miss Rose Hofmeister, formerly of Utica; a temporary nurse has served at night part of the time; the camp has also a cook to prepare the noon meal and the milk, eggs, etc., served at other hours of the day.

The camp opened with six patients and now has fifteen, the probable limit this year. The camp will be open until November 1st and perhaps longer. The design was to take only incipient and moderately advanced cases, but it has been difficult to draw the line in the new undertaking, and the camp has four patients with fairly advanced cases. One of them is confined to bed. Several patients sleep at the camp. The camp has received its patients from the municipal dispensary. Home supervision will be given by local organized charities.

The Albany camp, which it is expected will open soon under the supervision of the Albany Subdivision, will be situated on Kenwood Heights, on land generously furnished by the Albany Hospital for Incurables. The camp arrangements are in charge of a committee of which the medical members are Dr. Howard Van Rensselaer, Dr. Henry Hun, and Dr. Charles K. Winne. The camp's limit this first year, for the day camp alone, will be about fifteen patients. Incipient and moderately advanced cases only will be handled. The committee is, for purposes of cooperation, a subcommittee of the local Tuberculosis Committee of the State Charities Aid Association.

The New York city camp is to be conducted by the New York County Subdivision of the Red Cross, and will be established on the roof of the Vanderbilt Clinic. The clinic will fit up the roof and will supply medical supervision to the camp. The New York County Red Cross will supply nurses, attendants, and nourishment to the forty or more patients to be received. Inasmuch as the clinic is a member of the Association of the Tuberculosis Clinics of the city, the Red Cross will thus be brought into the organization. The camp will open on October 1st and will continue during the day all the year around. After the first few months. it is probable that it will be open day and night. The superintendent of the camp will be Mr. Charles B. Grimshaw, superintendent of the clinic, and supervision will be given by members of the regular staff of the clinic. The capacity of the camp will be at least forty and probably more patients. Patients with incipient and moderately advanced disease will be received, and when the camp is in operation for the whole twenty-four hours it is expected that more advanced cases can be handled.

The day camp idea is said to be really a contribution of the German Red Cross. It was adopted only after thorough investigation and after recommendation to the Red Cross by the National Association for the Study and Prevention of Tuberculosis. The day camp has been found to be of proved value in this country as well as abroad. The first day camp

in the United States was opened in Boston some three years ago, and has given such a good account of itself that it has been taken over by the new Consumptives' Hospital in Mattapan. Other camps have also been conducted in Boston, Salem, Mass., Washington, D. C., and New York (on the disused ferry boat Southfield, conducted last year by the Charity Organization Society and this year by Bellevue Hospitai). The camp has, in fact, come to be recognized as a valuable part of every progressive plan for the relief and control of tuberculous disease, and therefore offers a wide field for useful work on the part of an organization so large and influential as the Red Cross, while at the same time its relative inexpensiveness and simplicity of conduct will not require the raising of large sums or the maintenance of a large force of workers.

We learn that the Red Cross, national and local, has practically no funds with which to carry on this work, since it retains for its own use no part of the millions of dollars which pass through its hands, for they are given for the specific purpose of mitigating suffering in given localities, and since its membership dues are merely nominal and hardly meet the expense of organization. The relatively small emergency fund at national headquarters is available only for war and disaster, and the endowment fund only for national calamities of the greatest magnitude. The national charter does not permit of the deflection of the funds to such a use as that of the camps, and, moreover, it would not generally be deemed wise to do so. The Red Cross is therefore appealing for voluntary contributions, and we are confident that these contributions will be received in amounts sufficient to conduct a large number of day camps similar to those already instituted.

THE DANGERS OF CARBOLIC ACID DRESSINGS.

M. Salva Mercadé contributes to the July number of the Archives générales de médecine a useful summary of our present knowledge of the occasional untoward effects of certain antiseptics as they are employed in surgery and of the means of reducing them to a minimum. He begins with the consideration of carbolic acid, or phenol. This agent, now no longer the invariable accompaniment of surgical operations, has still, he thinks, all its pristine usefulness for spraying carbuncles and as a lotion after the incision of phlegmonous inflammations. In most cases it is from the use of solutions as a dressing that bad effects are observed, and their intensity seems to have no direct relation

to the strength of the solution. Gangrene, the most important of them, is clinically of the dry variety, coming on without pain, but changing the color of the integument to yellow, brown, or black. The tissues become dry and horny, and in two or three weeks the mortified parts separate. According to Levai, weak solutions are more dangerous than strong ones, for the reason that they do not cause such a degree of superficial induration as to interfere materially with the penetration of the agent. Most of the cases of gangrene have resulted from the use of solutions weaker than five per cent. The modus operandi is still uncertain; some observers think it is by the production of venous thrombosis, others interpret it as a toxic action on the trophic nerves, and yet others explain it as a chemical action producing coagulation of the albumin. The use of alkaline solutions at the outset has been advised to combat the tendency to gangrene, but usually the trouble has already progressed so far when medical aid is sought that only surgical measures are available.

General poisoning with carbolic acid may come on suddenly, even during the operation, or it may be slow in making its appearance, especially when phenol lotions have been employed to excess. It gives rise to violent headache, and convulsions have been observed. Loss of appetite is rapidly followed by nausea and vomiting. The respiration is modified, and the pulse becomes small. The urine is blackish. Pallor of the face is associated with sweats, coldness of the extremities, and reduction of the general temperature to 97°, 95°, or even 93° F. These phenomena are manifested within a few hours, and death takes place very rapidly. If recovery occurs, it is slow, occupying from eight to ten days. Besides these manifestations of grave poisoning, Prat has observed two instances of paralysis of accommodation in children who had been operated upon for hydatid cysts of the liver. In the first case recovery occupied three weeks after the use of phenol lotions had been stopped; in the other case it occurred immediately on the cessation of their employment.

The treatment is, above all, preventive; on no account must a phenol solution be allowed to stagnate on the surface of a wound. When signs of poisoning have been noted, the use of phenol must be stopped at once. In the acute form of poisoning the collapse may be combated by subcutaneous injections of ether, by caffeine, by frictions, and by hot water bags. The activity of the kidneys may be promoted by the free ingestion of liquids and by injections of serum. The internal employment of a five per cent, solution of sodium sulphate has been

recommended. Magnesium sulphate also may be used. By such treatment one may hope to engage the phenol in the formation of harmless phenolsulphates.

THE ÆTIOLOGY OF TYPHUS FEVER

It is seldom to-day that one has an opportunity to see a case of typhus fever, that serious disease which in former times was the cause of so many deaths in crowded institutions and camps. It has been said that the disappearance of typhus fever is a triumph for modern medicine, but it appears that nineteenth century sanitation is rather to be credited with it. Yersin and Vassal (Philippine Journal of Science, April) have had an opportunity to study a few cases. Among about a thousand coolies who had been imported into Nhatrang, Annam, from Tonquin there were five cases of a disease characterized by the sudden onset of fever with prostration and delirium, which continued for from ten to twelve days and then ended by crisis. In all the cases there was marked conjunctival injection. Although there was no rash, the authors diagnosticated these cases as typhus fever.

They tried in vain to reproduce the disease in laboratory animals, such as the rat, the guinea pig, and the rabbit. They then injected half a cubic centimetre of blood from one of the patients under observation into a healthy person of the same nationality; the donor was in the second day of the disease. In fourteen days the recipient had an attack of fever exactly like that from which the donor was suffering. The febrile paroxysm lasted for eleven days, giving a curve which was exactly like that shown in the naturally acquired disease, and ended by crisis in eleven days. There were no spots in this case, but the conjunctival injection was marked. This experiment was repeated in another person, the blood being obtained from the same donor as in the first experiment, on the fifth day of the disease. Half a cubic centimetre was injected into the recipient. In this instance the incubation period was twenty-one days. The clinical phenomena repeated themselves exactly, and the attack ended by crisis on the twelfth day. In diagnosticating these cases Yersin and Vassal have been careful to exclude spirillar fever, malarial fever, typhoid fever, kala-azar, and dengue.

The cause of the disease was not discovered, all investigations of the blood resulting in failure to find formed elements that could be considered in an ætiological relation. They suggest that the disease is probably transmitted by insects. Such an hypothesis would explain the extreme contagious-

ness in the old epidemics, and also the disappearance of the disease with improved sanitary conditions in the jails, asylums, and barracks in Europe and the United States.

KERATIN.

Dr. P. G. Unna and Dr. L. Golodetz, of Hamburg, have continued their researches and experiments with the horny substances (Monatshefte für praktische Dermatologie, July 15th). The first results of their studies we spoke of in our issue for September 28, 1907. Our authors used for their studies human horny material and cows' horn, and modify somewhat their former conclusion. They state that these substances are made up of keratin a, keratin 3, and soluble albuminous substances the composition of which has not yet been determined. Keratin a corresponds to the membrane of the horny cell, and forms the most resistant part of the cell. Chemically, it is generally composed of 53 per cent. of carbon, 7 per cent. of hydrogen, 14 per cent. of nitrogen, 1.75 per cent. of sulphur, and 0.6 per cent, of ash. Keratin 3 and the soluble albuminous substances form the contents of the horny cell, and are approximately composed of 48 per cent. of carbon, 6.5 per cent. of hydrogen, 15.6 per cent. of nitrogen, 2.2 per cent. of sulphur, and 0.5 per cent. of ash. An important distinction in the constitution of keratin α and keratin β is to be found in the high proportion of carbon in keratin a, about five per cent, higher than in keratin β . The horny layer of the human skin contains thirteen per cent. of keratin α and ten per cent. of keratin β , while the rest is formed by the soluble albuminous substances. Cows' horn contains about six per cent. of keratin α and thirty-six per cent. of keratin β , and the rest is soluble albuminous substances.

The authors sum up the results of their studies thus: While it has been so far the generally accepted opinion that the horny substances are especially distinguished in their chemical composition from other albuminous substances by a much higher proportion of sulphur (three to five per cent.), and the cornification been thought to proceed because of an increase of sulphur, it has now been proved that keratin a, which represents the last, the purest, and the most uniform product of cornification, is relatively poor in sulphur (containing about 1.75 per cent.). Even the proportion of sulphur in keratin β , which has less power of resistance and is not such a pure product, is relatively low. A high proportional amount of sulphur is, therefore, not a characteristic sign of horny products in distinction from other albuminous substances.

A CORRECTION.

In our last issue, in an article entitled The International Congress on Tuberculosis, we said: "The sessions are to open on September 21st and to continue until October 12th, but the section meetings will all be held during the week beginning on September 28th." Instead of "sessions are" we should have said exhibition is.

Rems Stems.

Changes of Address.—Dr. Carl A. Williams, from New London, Conn., to 14 Oreard Street, Worcester, Mass. The New Nurses' Home in Claremont, N. H., in connection with the General Hospital, was dedicated with suit-

able exercises on August 21st.

The Alvarenga Prize of the College of Physicians, Philadelphia, has been awarded to Dr. William T. Shoemaker, of Philadelphia, for an essay on Retinitis Pig-

International Congress for School Hygiene.—The third International Congress for School Hygiene will be opened at Paris, France, March 29, 1910. For all information in regard to the congress apply to Dr. R. Dinet, rue

Cermuschi, Paris, France. Charitable Bequests .- By the will of Mrs. Randolph

Townsend, who died recently in Rugby, England, the Samaritan Hospital, Troy, N. Y., will receive \$50,000.

By the will of Mrs. Mary A. Baird, the Litchfield County Hospital, Winsted, Conn., will receive \$10,000.

Cholera in Russia.-According to press despatches, cholera is spreading in Russia, and has reached the city of Lodz, in Russian Poland. The German health authorities have increased their vigilance, and hundreds of medical inspectors have been stationed along the eastern frontier.

The Elmira, N. Y., Academy of Medicine.—The regular meeting of this academy was held on Wednesday evening, September 2d. The programme included a paper by Dr. J. A. Westlake entitled The X Ray in the Treatment of Cancer, and a paper by Dr. W. S. Cain on Typhoid Fever.

Examination for Medical Superintendent of Craig Colony.—The New York State Civil Service Commission announces that an examination will be held on September 26th from which to make certification to fill the position of medical superintendent of the Craig Colony for Epileptics. Sonyea. N. Y., made vacant by the recent resignation of Dr. William P. Spratling.

The New Corps of Nurses for the Navy.- It is reported that one of the first drafts of female nurses, from the new corps that is soon to be formed from graduates of schools of nursing, after passing the required examinations, will be made for the Naval Hospital at Canacao, Cavite As soon as practicable also a number of nurses will be sent to the Naval Hospital at Yokohama, Japan.

The Uniform of the Army Medical Reserve Corps. It has been prescribed by the War Department that the uniform for the officers of the Army Medical Reserve Corps will be the same as that of officers of the Medical Corps, except the insignia, which will be the caduceus of gold or gilt, superimposed in the centre by a monogram of dull finish bronze, bearing the letters R. C., for the full dress, dress, and white coats. For the service coats the caduceus will be of dull finish bronze metal, superimposed in the centre by the monogram in gold or gilt

The China Medical Missionary Association.-Plans are being made for the next meeting of this association, which is to be held in Hankow in the spring of 1910. members of the Central China Medical Missionary Assomembers of the Central China Medical Missionary Asso-ciation will constitute a Committee on Arrangements and Entertainment, with power to appoint a local Executive Committee. A Committee on Programme has been ap-pointed, the members of which are required to secure papers to be read at the meeting of the association. An important question to be discussed at this meeting is the advisability of accepting Chinese graduates as members of the association

Contagious Diseases in Chicago .- During the week ending August 22, 1908, there were reported to the Department of Health the following cases of transmissible diseases: Diphtheria, 60 cases; scarlet fever, 38 cases; measles, 16 cases; chickenpox, 2 cases; typhoid fever, 20 cases; whooping cough, 8 cases; tuberculosis, 41 cases; minor diseases, 2 cases; total, 187 cases.

The Health of Michigan .- During the month of July, 1908, the following cases of communicable diseases were reported to the State Department of Health: Pneumonia, 52 cases; tuberculosis, 47 cases; typhoid fever, 110 cases; diphtheria, 69 cases; meningitis, 32 cases; whooping cough, 75 cases; scarlet fever, 96 cases; measles, 151 cases. There were 70 deaths from pneumonia and 207 deaths from tuber-

culosis during the month. Phonographic Lectures on Tuberculosis.-The phonograph is to appear in a new rôle. The New York State Charities Aid Association has prepared six traveling tuberculosis exhibitions, which are to be shown at all the county fairs held in the State, and in connection with the exhibition a large talking machine will be used to tell the people something about the prevalence of tuberculosis in the State, the cause of its spread, the means whereby it may be prevented, and how it may be cured. Selections from comic operas and popular airs will be interspersed with these talks on tuberculosis.

Scientific Society Meetings in Philadelphia for the

Week Ending September 12, 1908: Monday, September 7th.—Philadelphia Academy of Sur-gery; Biological and Microscopical Section, Academy of Natural Sciences; West Philadelphia Medical Asso-

ciation; Northwestern Medical Society.
Tuesday, September 8th.—Philadelphia County Medical

Society.

Wednesday, September 9th.—Pathological Society.
Thursday, September 10th.—Northern Medical Association; West Branch, Philadelphia County Medical Society.

Officers of the American Public Health Association.-At the annual meeting of this organization, which was held in Winnipeg, Canada, during the week of August 24th, the in Winnipeg, Canada, during the week of August 24th, the following officers were elected for the ensuing year: Presi dent, Dr. Gardner T. Swarts, of Providence, R. I.; first vice president, Dr. R. M. Simpson, of Winnipeg; second vice president, Dr. Jesus Chico, of Mexico; third vice president, Major Charles F. Mason, of the Medical Corps of the United States Army; secretary, Dr. Charles O. Probst, of Columbus, Ohio; and treasurer, Dr. Frank W. Wright, of New Hayen, Coun. The association will meet next year in New Haven, Conn. The association will meet next year in Richmond, Va.

The Fourth International Electrotherapeutic Congress was held in Amsterdam during the past week, under the presidency of Dr. J. K. A. Salomonson, professor of neuro-pathology in the University of Amsterdam. The first congress was held in Paris in 1900, the second in Berne in 1903, and the third in Milan in 1905. The congress was divided into four sections, namely: Electrophysiology and pathology, diagnosis and therapeutics by electrical methods. diagnosis and therapeutics by x rays, and the study of various radiations and the technic of electrotherapeutics. The formal title of the association is Congrès International de Radiologie et d'Electrologie Médicales.

A New Nurses' Home for the Kings County Hospital. —Plans are being prepared for a new nurses' home and training school for nurses, to be erected on the grounds of the Kings County Hospital, Brooklyn. The site, which is at the westerly end of the grounds and fronts on Clarkson street, near New York avenue, is 105 feet long and 110 feet deep. The building will be five stories high, and will be constructed of red brick, with limestone and terracotta trimmings. On the first floor will be the quarters of the superintendent, a library, demonstration classrooms, study rooms, a lecture hall, two reception rooms, the nurses' dining room. and several bedrooms. The second, third and fourth floors will be occupied by bedrooms, and on the fifth floor will be a gymnasium and a sun parlor. The work of construction will be begun this fall, and it is expected that the building will be ready for occupancy in about a year from now. The building of the Nurses' Home is only one of the many improvements planned for the Kings County Hospital, the facilities of which are entirely inadequate to meet the demands made upon it

The Health of Pittsburgh .- During the week ending August 22, 1908, the following cases of transmissible diseases were reported to the Bureau of Health of Pittsburgh: Chickenpox, 5 cases, o deaths; typhoid fever, 31 cases, 3 deaths; scarlet fever, 13 cases, 1 death; diphtheria, 7 cases, 2 deaths; measles, 9 cases, I death; whooping cough, 3 cases, I death; pulmonary tuberculosis, 17 cases, Io deaths. The total deaths for the week numbered 145, in an estimated population of 565,000, corresponding to an annual death rate of 13.34 in 1,000 of population.

Personal.-Dr. William W. Keen, of Philadelphia, who has been abroad for more than a year, has returned home. Sir William Macewen, F. R. S., M. D., regius professor of surgery in the University of Glasgow, has been appointed

by King Edward to be one of the honorary surgeons in Scotland, in the place of Sir Patrick Heron Watson, M. D.,

Dr. Samuel S. Bernheim, of Paris, president of the French Society for the Study of Human Tuberculosis, arrived in New York on August 31st. He was deputed by the French Government to attend the International Tuberculosis Congress, but, before going to Washington, Dr. Bernheim will visit the principal cities of the United States and investigate the sanitary measures employed in American factories to prevent the spread of tuberculosis.

Society Meetings for the Coming Week:
Monday, September 7th.—Utica, N. Y., Medical Library
Association; Niagara Falls, N. Y., Academy of Medicine; Practitioners' Club, Newark, N. J.; Hartford,

cine; Practitioners' Club, Newark, N. J.; Hartford, Conn., Medical Society.

TUESDAY, September 8th.—Medical Society of the County of Schenectady, N. Y.; Practitioners' Club of Jersey City, N. J.; Medical Society of the County of Rensselaer, N. Y.; Buffalo Academy of Medicine (Section in Medicine); Newburgh Bay, N. Y., Medical Society in Medical Society of the Borough of the Bronx, New York; Brooklyn Medical and Pharmaceutical Association; Medical Society of the County of Richmond N. Y.

County of Richmond, N. Y. THURSDAY, September 10th .- Blackwell Medical Society of

Rochester, N. Y

The Mortality of Chicago .- According to the report of the Department of Health of the City of Chicago for week ending August 22, 1908, the deaths from all causes reported to the department during the week was 575, which was 45 less than for the previous week and 109 less than for the corresponding period in 1907. The annual death rate in 1,000 of population, in an estimated population of 2,166,055, was 13.84, as compared with a death rate of 16.92 for the corresponding week in 1907. The principal causes of death were: Apoplexy, 12 deaths; The principal causes of death were: Apoplexy, 12 deaths; Bright's disease, 34 deaths; bronchitis, 4 deaths; consumption, 53 deaths; cancer, 32 deaths; convulsions, 5 deaths; diphtheria, 3 deaths; heart diseases, 34 deaths; intestinal diseases, acute, 196 deaths; nervous diseases, 10 deaths; pneumonia, 27 deaths; searlet fever, 5 deaths; suicide, 7 deaths; sunstroke, 3 deaths; typhoid fever, 5 deaths; violence, other than suicide, 28 deaths; whooping cough, 4 deaths; all other causes, 112 deaths. deaths; all other causes, 113 deaths

The Health of Philadelphia.-During the week ending August 22, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Typhoid fever, 65 cases, 6 deaths; malarial fever, 1 case, 1 death; scarlet fever, 13 cases, o deaths; chickenpox, I case, I death; diphtheria, 42 cases, 2 deaths; measles, 15 cases, 3 deaths; whooping cough, II cases, 5 deaths; pulmonary tuberculosis, 97 cases, 41 deaths; pneumonia, 23 cases, 12 deaths; erysipelas, 2 cases, 0 deaths; puerperal fever, 2 cases, 2 deaths; cancer, 21 cases, 28 deaths; mumps, 2 cases, 0 deaths; mumps, 2 cases, 0 deaths. The following deaths were reported from other transmissible diseases: Tuberculosis, other than that of the lungs, to deaths; diarrhox and enteritis, under two years of age, 81 deaths. The total number of deaths from all causes was 490, in an estimated population of 1,532,738, come pending to an annual death rate of 16,62 in 1,000 of The total infant mortality was 166; 138 under one year of age, and 28 between one and two years of age.
There were 46 still births, 25 males and 21 females.
Vital Statistics of New York.—During the week end-

ing August 22, 1908, there were reported to the Department of Health of the City of New York 1,385 deaths from all causes, as compared with 1,334 for the previous week, and 1,600 for the corresponding period in 1907. The number of deaths in each of the five boroughs was as follows: Manhattan, 726; the Bronx, 104; Brooklyn, 437; Queens, 73; and Richmond, 45. The annual death rate in 1,000 of population was 16.34, in an estimated population of 4,104,304, as against a death rate of 19.48 for the corresponding period in 1907. The death rate of Brooklyn was the lowest of the five boroughs, being 15.27; while that of Richmond was the highest, being 30.61. The death rate of Manhattan was 16.52; of the Bronx, 16.56; and of Queens, 16.37. the total number of deaths 600 were of children under five years of age, and of these 328 were due to diarrheal diseases. There were 153 deaths from pulmonary tuberculosis, as against 149 for the corresponding week in 1907. were IIO violent deaths: 4 from sunstroke, 4 from homicide, 16 from suicide, and 86 from accidents. Four hundred and twenty-eight marriages, 2,486 births, and 132 still

births were reported during the week.

The Mississippi Valley Medical Association.—The thirty-fourth annual meeting of this association will be held at the Seelbach Hotel, Louisville, Ky., on October 13, 14, and 15, 1908. The preliminary programme, which has just been issued, includes a long list of papers on subjects of interest to the general practitioner, and judging from the titles of the papers and the high standing of their authors, the meeting promises to be one of unusual interest and value. Ample entertainment has also been provided for the visiting physicians and their friends. The address of welcome on behalf of the State will be delivered by the Hon. A. E. Willson, governor of the State of Kentucky; the address of welcome on behalf of the city of Louisville will be delivered by the Hon. James F. Grinstead, mayor of the city; and the address on behalf of the local profession will be delivand the address on behalf of the local profession will be delivered by Dr. Lewis S. McMurtry. The address in medicine will be delivered by Dr. George Dock, of Ann Arbor, Mich., on Tropical Disease in the Mississippi Valley, and the address in surgery will be delivered by Dr. Arthur Dean Bevan, of Chicago, on the Surgery of the Kidney. The officers of the association are: President, Dr. Arthur R. Elliott, of Chicago; first vice president, Dr. F. F. Law-rence, of Columbus, Ohio; second vice president, Dr. R. C. McChord, of Lebanon, Ky.; secretary, Dr. Henry Enos Tuley, of Louisville, Ky.; and treasurer, Dr. S. C. Stanton, of Chicago.

An International Congress for the Suppression of Food and Drug Adulteration.—The first international congress for the suppression of adulteration of food stuffs and pharmaceutical preparations will be held in the University of Geneva, Geneva, Switzerland, on September 8th, and last four days. The objects of this congress, the first of its kind. are to promote the establishment of uniform, international standards of purity for food stuffs and pharmaceutical products, and to formulate the measures which should be taken to suppress the various forms of adulteration and sophistication which are so prevalent. The programme is very comprehensive. Food stuffs, for example, will be considered under three groupings, as follows: (1) Wines, alcoholic beverages, beer and cider; (2) milk, butter, cheese. meats, tinned goods, etc.; (3) cocoa, coffee, tea, flour, sugar, spices, pastries, etc. Another group will include natural and artificial mineral waters, soda beverages, crude drugs pharmaceutical and galenical preparations. The aim of the pharmaceutical and galenical preparations. The aim of the congress has received the active support of the various governments, the following list of adherents being from the United States: Dr. H. W. Wiley, chief of the Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.; Dr. S. T. Armstrong, general medical superintendent of Bellevue and Allied Hospitals, New York; Dr. W. D. Bigelow, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.; Dr. L. F. Kebler, U. S. Department of Agriculture, Washington, D. C.; Dr. H. H. Rusby, College of Pharmacy Columbia University. New York: Dr. College of Pharmacy, Columbia University, New York; Dr. Henry M. Whelply, of St. Louis; Dr. L. E. Sayre, of Lawrence, Kansas; Dr. E. H. Jenkins, of New Haven, Conn.; and Mr. B. T. Fairchild, of New York. The congress owes its existence to the activity of the Universal Society of the White Cross of Geneva, which was founded some time ago for the purpose of accomplishing in time of peace what the Red Cross Society is organized to do in time of war. The general aim is to unite all the efforts made in different countries to combat infectious diseases, tuberculosis, social ills caused by drink and adulteration of food stuffs, and diseases due to poverty, squalor, etc. The fee for titular membership is \$4 and ordinary membership \$1.20. Dr. H. W. Wiley, of Washington, D. C., chairman of the American committee, will undertake to forward names of members and their subscriptions.

THE BOSTON MEDICAL AND SURGICAL JOURNAL

August 27, 1908.

The Psychopathic Hospital and Psychiatrical and Neurological Wards, By Philip Coombs Knapp. Remarks upon the Present Status of Sanatorium Treatment for Tuberculosis,

By VINCENT Y. BOWDITCH.

By Julius Friedenwald. Gastromyxorrhœa, Renal Insufficiency; The Importance of its Early Recognition, By S. M. RANDALL. Recognition.

Gastromyxorrhœa.-Friedenwald describes this disease and its treatment. It designates the presence of small quantities of mucus appearing occasionally in the fasting stomach, and it may be intermittent or continuous. The ætiology is doubtful. In intermittent cases the mucus may come from the nose, mouth, pharynx, in continuous it may be a mixture of the secretion of the superficial epithelium and of the mucous glands. The attack of intermittent gastromyxorrhœa may begin with headache, loss of appetite, nausea, etc., but more usually begins in the midst of perfect health, often early in the morning soon after awakening. The most striking symptom of this paroxysmal attack is severe vomiting, which is intractable in the true sense of the word, inasmuch as it cannot be successfully combated by any remedy. The vomited matter consists of large quantities of tough, slimy liquid. finally of bile and intestinal juices, but contains no food remains. Pain in the region of the stomach is not present, or if it is, it is of no moment. During the attack the stomach refuses to retain food, drink, or medicine. The patient feels wretched, the abdomen is retracted, the pulse small, the tongue dry, and the quantity of urine much diminished. The attack may extend over a period of one day, or may continue from three to five or even twelve days. The attack usually ceases quite suddenly, and after the cessation of the vomiting, the patient can again take food without any annoyance. The patient enjoys good health during the interval of the attacks and often has none or very slight dyspeptic symptoms. The examination of the gastric contents after a test breakfast in the interval generally reveals a normal percentage of hydrochloric acid and only a slight amount of mucus. It has been stated that lavage of the stomach may, when given at the beginning, terminates the attack. Friedenwald has had no success with lavage. Morphine given hypodermically often gives temporary relief, and in cases of extreme exhaustion and weakness, normal salt solution enemata or infusions may be indicated. Between attacks attention should be directed to the underlying condition; that is, to the neurotic tendency, and for this purpose change of climate, hydrotherapy, massage, and electricity, as well as iron and arsenic, have been recommended. Inasmuch as this disorder may be secondary to diseases of other organs, a careful investigation should be made as to the primary disorder, which, if possible, should be relieved.—There are no characteristic symptoms of continuous gastromyxorrhœa, and the condition may be discovered in some cases even in which

there are no subjective symptoms whatever. The diagnosis is established by the discovery of large quantities of mucus in the fasting stomach, shown to be the product of the gastric mucous membrane, and not originating from other sources, such as the nose, mouth, or pharynx. It is of no importance whether subjective symptoms are present or not. Lavage should be practised for the removal of the mucus providing there is no contraindication to this procedure; instead of this method of treatment administration of mineral waters is advised by some, these being chosen with reference to the nature of the associated disease, the general condition of the patient, and of the various gastric functions.

- Röntgenology in Neurology. Kassabian
- states that the Röntgen rays have been invaluable in detecting the ætiology of nervous manifestations, the result of disease of the osseous system. The rays are not a substitute for, but only an adjunct to, the neurologist's investigations. Changes occurring in the osseous system (resulting in neurological symptoms) are readily detected by the rays. The distinctive diagnosis between epiphysitis and neuritis is readily accomplished. Osteitis and periostitis are readily distinguished and diagnosticated by this agent. Neurological conditions dependent on old and unreduced fractures and dislocations, and pressure symptoms from excessive callus formation, are now readily diagnosticated. Supernumerary ribs and vertebræ formerly so rarely diagnosticated during life are easy of detection by the x rays, as is their distinction from aneurysm. Osseous tumors and exostoses are easily discernible. Troublesome pressure symptoms are thus readily accounted for. Osseous atrophy and hypertrophy are recognizable by the x rays, and their study is important because of the diseases with which these conditions are associated. The osseous changes occurring in acromegaly and

cretinism are well brought out skiagraphically and are easy of distinction. The value of the Röntgen rays is of paramount importance in determining changes occurring in the articular system, whether due to pathological states in, near, or around a joint, as in the study of arthropathies, spinal joint affections, etc. The arthropathies of the tabes and dementia paralytica form an interesting study from a Röntgen ray viewpoint. The early, mild, advanced, and severe types of arthropathies present varying Röntgenograms. The distinctive diagnosis between tabes dorsalis and arthritis deformans presents a widely contrasting picture by the use of the rays. Brain tumors, clots, and cysts are more difficult of interpretation. Soft tissues do not cast shadows so dense as do the harder tissues, the growth is within a bony cage and may be far from the plate. Similarity of symptoms arising from aneurysms and mediastinal tumors are frequently distinguished by a skiagram. The skiagraphic detection, localization, and extraction of foreign bodies will frequently explain existing neurological manifestations. Dental studies have greatly progressed since the introduc-tion of the x rays. The headaches, neuralgias, etc., so often dependent on unerupted teeth, malpositions, etc., are now readily detected and remedied. The therapeutic action of the Röntgen rays is evidenced in their analgesic action, in their palliative and often curative effects in neuralgia, and in their causing an absorption or decrease in size of various growths and neoplasms. Painful pressure symptoms are thus mitigated.

3. Experiments on an Ash Free Diet and Salt Metabolism.—Joslin and Goodall have made studies on ash free diet and salt metabolism. They find that the withdrawal of salt from the body does not lead to the production of acid intoxication of the diabetic type nor does it increase an acidosis already existing. Œdema in cases of diabetes mellitus presenting marked acidosis frequently occurs coincident with restriction of the carbohydrates in the diet. This cedema is not due to the simultaneous administration of sodium bicarbonate, but it is probably caused by the increased production of acids causing injury to the kidneys during excretion, thereby leading to retention of salt. Patients in diabetic coma almost without exception present no signs of ædema, and show diminished chlorine in the urine if alkalies are given. The careful administration of salt along with sodium bicarbonate is recommended in the prophylactic and actual treat-

ment of diabetic coma.

7. Obstetric, Septic, and Anæsthetic Toxæmias.—Wetherill's reading, observation, and clinical experience lead him to believe that toxæmias of pregnancy, sepsis, sapræmia, late chloroform poisoning, etc., have many common characteristics, and from the standpoint of the clinician they may be grouped for study, prevention, and treatment. Chloroform may cause such toxæmias and liver lesion de novo; it aggravates existing toxæmias of the hepatic type. Pregnancy, retained blood, and clots of concealed hæmorrhage, the sapræmia from decomposing placental and fætal débris, sepsis, and the autointoxication of overfeeding and drinking and objectives and contraction of overfeeding and drinking and objectives are contracted to such liver lesions.

sions. Urinary insufficiency with acidosis and a high ammonia coefficient, retinal hæmorrhages and neuroretinitis, regurgitant vomiting of the mucous, bilious, grumous type, with or without slight jaundice, and with or without albuminuria, constitute the syndrome characteristic of such toxemias. Albuminuria, when it occurs, may be, and often is, late in developing, and should be regarded as secondary rather than primary, and as a result rather than a cause of the condition. In such toxemias of pregnancy with or without pernicious vomiting the uterus should be emptied at once, but without chloroform, and, if possible, without other anæsthesia. Fasting and forced elimination by the skin, kidneys, and bowels offer the best prospects for cure after, as well as before, the removal of the cause.

9. New Sign of Malingering. - Hoover observes that if a normal person, lying on a couch in the dorsal position, is asked to lift the right foot off the couch with the leg extended, the left heel will be observed to dig into the couch as the right leg and thigh are elevated. If you place your hand under the tendo Achillis of the left side and sense the muscular resistance offered by the left leg you will observe that the left heel is pressed on to the couch with the same force which is exhibited in lifting the right leg off the couch. In other words, the left heel is employed to fix a point of opposition against the couch during the effort at lifting the right leg. This will always occur if a healthy person makes a free and uninhibited effort to lift the right leg. If the movements are carried out in the reverse order the same principle holds true; i. e., if a normal person is requested to press the right leg against the surface of the couch there will be a counter lifting force exhibited in the left leg. If a patient suffering from hemiplegia or monoplegia of a leg is requested to lift the extended and paretic leg off the couch it will be observed that the other leg offers the opposition described whether there is any voluntary muscular strength exhibited or not on the affected side. If the hemiparetic patient is asked to lift the normal leg off the couch against resistance he will exhibit an opposition with the paretic leg which is directly proportional to the voluntary muscular strength he is able to employ when a display of voluntary muscular power in the paretic leg is exacted. When the upper extremity is involved this sign is sometimes demonstrable on the normal arm, but at other times it is wanting. In two cases in which paresis of one leg was alleged by the plaintiffs in suits for personal injuries, there were wanting the characteristic physical signs to sustain the assertion of paresis of the lower extremity as the result of injuries. In both of these cases, when the patient was asked to lift the normal leg off the couch, the leg which was alleged to be very paretic was opposed strongly against the surface when resistance was offered to lifting the normal leg. When the patient was requested to lift the paretic leg, there was an apparent attempt to respond to the author's demand, but the normal leg did not offer the least opposition. The normal leg lay perfectly limp on the couch. Had the paresis been genuine, the sound leg would have been firmly opposed against the surface of the couch when an uninhibited attempt was made to lift the paretic leg.

MEDICAL RECORD

August 29, 1908.

Plague: Mode of Dissemination and Methods for Control, By J. C. Perry.
Simplification of the Jacoby-Solms Ricin Method

A Simplification of the Jacoby-Solms Ricin Method for Pepsin Determination, By Max EINHORN. Tuberculosis Other than Pulmonary Treated with Tuberculin—Report of Cases, By G. R. Pogue. Early Diagnosis of Carcinoma of the Sigmoid.

By EDWARD MILTON FOOTE
The Painful Cutaneous Zones in Visceral Disease, By M. D. BLOOMFIELD.
Four Cases of Perforating Ulcers of the Alimentary Canal, By H. BEECKMANN DELATOUR.

r. Plague.—Perry observes that in towns threatened with plague sanitary measures should be instituted to place them in as good a condition as possible from a rat standpoint. The effective way to repel an invasion is to be prepared to meet it. A careful watch should be maintained in order to detect unusual mortality among rats, and upon the appearance of the disease in these animals the most energetic measures should be instituted to eradicate the infection. Rat plague should receive the same consideration as if the cases were in man. Plague is generally introduced in healthy localities (I) by rats and their fleas, and (2) by infected cargo or food, man and his effects being of secondary importance. Plague is transmitted from rat to rat by fleas, and these insects are also responsible for the transmission of plague to man in the majority of instances. The most effective measures for the control of the disease in infected centres are rat

destruction, evacuation, and inoculation.

2. A Simplification of the Jacoby-Solms Ricin Method for Pepsin Demonstration.—Einhorn has simplified the Jacoby-Solms ricin test. His apparatus consists of a cylindrical glass, surrounded by a vacuum. This glass tube contains a frame holding twelve graduated pepsin tubes. The whole apparatus can be filled with water and corked. Each pepsin tube is marked with a different letter and shows a mark at 2 c.c., 3 c.c., and 3.5 c.c. The lower part is, furthermore, graduated into millimetres. Thus we may dispense with pipettes and measuring glasses. Use it as follows: Fill each pepsin tube up to 2 c.c. with I per cent. ricin solution, then add up to the 3 c.c. mark filtered and diluted stomach contents, and finally add decinormal hydrochloride acid solution up to 3.5 c.c. The tube is well corked, shaken up thoroughly, and then placed into the frame. The letters on the tubes identify the various dilutions. The vacuum tube is filled with fairly hot water (50° to 60° C.), the frame with the pepsin tubes is placed in it, then the apparatus is corked and allowed to stand for half an hour. Observations are taken of the time at which the deposits in the various tubes disappear and are noted. After thirty minutes the amount of precipitate left in any of the tubes is recorded. The advantage of the modification lies in the fact that the test is simpler, that a thermostat is not needed, and that it consumes less time. In making the test, the dilutions of 10, 20, 40, and 100 are most serviceable. Normally, the precipitate disappears in a dilution of 10 or 20. If a precipitate is present at 10 the pepsin is diminished, if it disappears at 40 the pepsin is increased. In achylia or marked subacidity the filtrate is used undiluted or only slightly diluted (2 to 5 times).

3. Tuberculosis Other than Pulmonary Treated with Tuberculin.-Pogue reminds us that the capsule of the tubercle is a nonvascular fibrous structure, which serves two purposes: It protects the tissues against the growing and multiplying bacilli; it also protects those same bacilli from the bactericidal substances that may be present in the tissues. whether those substances are the product of natural or artificial immunity. Recently we have heard much about producing immunity by the use of certain tubercle bacilli products introduced into the system, but investigation shows that any immune bodies thus produced have no action upon the encapsulated bacilli. We cannot get around the fact that Nature's way of arresting and curing tuberculosis is the only method by which we may hope to win, viz., by encapsulation, and this encapsulation must be complete. In visible tuberculosis, as of the eye, pharvnx, larvnx, or mucous membrane, it has long been noticed that some hours after an injection of any of the tubercle bacilli products, in small doses, a congestion is always produced around the tubercles. Such hyperæmia aids in the production of new tissue to the capsule, where Nature has already made an attempt to protect the host. This is what might be considered as the second physiological action of tuberculin. In the stimulation of the production of tuberculoopsonins, Wright has shown the necessity for the small dose. The same small dose produces the hyperæmia around the tubercle. Seven years' experience with tuberculin. used in small doses, has convinced one of its value in properly selected cases. At no time has the author found it necessary to increase the dose to anything like that advocated by some writers. Tubercle bacilli preparations seem to have a double action when introduced into the circulation of a tuberculous individual, especially in the early stages of the disease: (1) The stimulation of the production of tuberculoopsonins, which opsonins have a certain unknown action on tubercle bacilli that are free in the tissues, so preparing them that they are readily taken up and presumably destroyed by the phagocyting leucocytes. (2) The causing of a hyperæmia around the tuberculous area, thus aiding the process of encapsulation. In both cases the small dose, is called for. We have only begun to learn. in a small way, the value of tubercle bacilli products in the treatment of tuberculous lesions. the physiological and therapeutic action of the drug becomes better understood, its application in suitable cases will become more general. Tuberculin can never be considered a specific in tuberculosis. but at the present time we know it as a most valuable adjuvant to other well recognized therapeutic agents in the treatment of tuberculous lesions in the early stages of the disease. When tuberculin was first introduced by Koch, its properties and action were practically unknown. Each man who used it seemed to have his own ideas as to dosage and physiological action. Even to-day we know but little about its physiological action, but there seems to be a more rational idea as to dosage. The work of Wright has given us an explanation of the action of tuberculin which seems very feasible, especially under certain conditions, viz., when the tubercle bacilli are free in the tissues and can come in contact with the body juices and the phagocyting leucocytes, as in open tuberculosis. In closed tuberculosis, conditions are different. A diagnosis of tuberculosis can never be made until after tubercle formation has taken place. Not only has tubercle formation taken place, but very probably many generations of tubercles have formed and ruptured before the lesions have become large enough to produce symptoms from which we could make a diagnosis.

1. Pyopericardium in Children. - Poynton states that pyopericardium in young children may occur in a general pyæmia, as a sequence to a local infection, complicating, for example, suppurative otitis media, osteomyelitis or septic wounds. In such cases septic abscesses may be found throughout the Pericarditis under such circumstances is a deadly complication. In young children, under twelve years of age, pyopericardium is almost invariably associated with pulmonary disease, which is most commonly pneumococcal in origin. The condition is met with in males and females equally, but eighty-three per cent. occur before the fourth year of life is completed, and two thirds (sixty-six per cent.) between the ages of one and three years. Primary pyocardium is excessively rarc. Diagnosis is beset with difficulties. The first one is the usual absence of pericardial friction. The poisons leading to pyopericardium have a more peptonising or digestive power than the rheumatic; and so the exudations are softer and more creamy in consistence and less harsh-hence friction is much less frequent. The early age of the patient furnishes another great difficulty in diagnosis. Then there are almost invariably signs of severe pulmonary disease, such as pneumonia, pleurisy, and empyema, all of which distract attention from the heart. Lastly there is the absence of endocarditis. The cases may be grouped into three classes: 1. The acute, running their course in about four weeks, and including twenty

per cent. 2. The subacute, lasting from four weeks to six months, and including fifty per cent. 3. The chronic, with insidious onset lasting from six months to over a year, and including seventeen per cent. Among the more important signs are progressive muffling of the heart sounds synchronous with enlargement of the cardia area, together with marked percussion dulness over the pericardium and sometimes posteriorly in the interscapular region. Tubular breathing or absent breath sounds may also be noted in the interscapular region. 2. A rapid and extensive increase of the cardiac dulness upwards towards the left clavicle. 3. The pearshaped outline of a distended pericardium. 4. The abrupt transition from the dulness of fluid to resonant lung tissue. 5. A wavy and diffuse pulsation to the left of the sternum. The most common error in diagnosis is the mistaking of half truth for the whole-stopping short at pneumonia or empyema. Another mistaken diagnosis is tuberculosis. The prognosis of suppurative pericarditis in small children is exceedingly grave, and unless a specific serum be obtained, improvements in diagnosis will not help us in treatment. Surgical intervention at present offers the best chance of success.

2. Pneumonia in Children.—Dunlop's article is based on a series of 500 cases of pneumonia in children. Of these 147 were of the lobar variety, 85 occurring in boys, and 62 in girls. An immense majority of these cases occurred in the winter and spring months. Forty-five cases occurred in children under two years old. Distant, faint, or absent breathing, or breathing of an indeterminate or jerky character accompanied by an almost tympanitic percussion note, is very typical of an early pneumonia, especially when accompanied by harsh puerile breathing on the opposite side. The crepitant râle, so distinctive of the early stage of pneumonia in the adult, is more frequently absent than present in the child, and the physical signs may disappear with extreme rapidity. Pain is a common symptom but is apt to be referred to the abdomen rather than to the thorax. Convulsions occurring at the commencement of the disease, and replacing the chill in the adult, are not of great moment. But convulsions occurring late in the disease almost invariably herald an early fatal issue. Convulsions rarely occur in children over two years of age. Extreme slowness and irregularity of the pulse in convalescence, indicates a profound toxemic influence of the pneumococcus on the cardiac muscle. Empyema is the commonest complication. Of the 353 cases of bronchopneumonia, 120 were primary, and 233 secondary. The diagnosis is often difficult. The following points aid in differentiation from lobar pneumonia: (1) The more disseminated character of the lesion in the lung, (2) the remissions in the temperature, (3) the greater amount of cyanosis and dyspnœa, and (4) the more troublesome character of the cough. Auscultation is more reliable than percussion, and every inch of lung should be examined, as the pneumonic patches are often very small. Unlike in lobar pneumonia, resolution usually takes place very slowly. The following are the chief points to be considered in estimating the prognosis: 1. The primary disease; those cases which occur after measles, whooping cough and diphtheria, were exceedingly fatal, giving a death rate of 54.4 per cent. 2. The younger the child the worse the prognosis; 64.4 per cent. of the deaths occurred in children under two years of age. 3. The greater the extent of the lungs involved the less is the chance of recovery. In seventy-three per cent. of the deaths, both lungs were affected. 4. The poorer the previous health of the child the graver the prognosis. In the great majority of deaths the children were wretchedly nourished and developed. 5. When a child suffers from severe forms of rickets the prognosis is always grave. In thirty-four per cent. of the deaths severe rickets existed. 6. Diarrhœa seriously affects the prognosis. This condition was present in twenty-four per cent. of the deaths. 7. A temperature of 105° F. adds greatly to the gravity of the case; 60 per cent. of these cases died. 8. A pulse rate over 180, and a pulse respiration ratio of 1 to 2, or 1 to 11/2, is always serious. 9. The highest mortality was in the cases which had lasted for several weeks.

Phagocytosis in Human and Horse Serum. 5. Phagocytosis in Fullian and Shattock and Dudgeon have investigated the rise in the opsonic value of the blood that takes place when horse serum is administered to the human subject. Their conclusions are as follows: The opsonic value of normal horse serum is decidedly lower than that of normal human serum or than that from patients suffering from chronic pulmonary tuberculosis. There is nothing noteworthy in the behavior of horse serum as studied by saturation with deopsonising agents. Saturation with Staphylococcus pyogenes aureus or with Bacillus coli considerably reduces the phagocytosis towards both these organisms. Saturation with human red blood has a somewhat similar effect in regard to both the microorganisms named. Horse serum does not increase phagocytosis by reason of the agglutinin it contains, as distinguished from its opsonin, as heating the serum to 60° C. (which removes the opsonin but leaves the agglutinin) so markedly reduces phagocytosis that this possible factor is negligible. The admixture of horse serum to normal human serum in vitro does not, after incubation, raise the opsonic value of human serum, but on the contrary reduces it. The admixture of horse serum to the serum of a patient suffering from chronic pulmonary tuberculosis does not after incubation in vitro raise the opsonic value of the tuberculous serum. The admixture of horse serum to the serum of a patient suffering from chronic pulmonary tuberculosis does not after incubation in vitro and allowing the immune cells to work in the mixture raise the opsonic value of tuberculous serum.

6. Excision of the Tonsil.—Upcott discusses the extrabuccal removal of malignant growths of the tonsil. The following is a summary of the steps of the operation in the case of a medium sized growth of the tonsil without obvious glandular enlargement. 1. While the patient is being anæsthetized inject subcutaneously 1/100 grain of atropine. Perform tracheotomy or laryngotomy, and pack the pharynx and mouth with gauze (this may be deferred to a later stage if thought necessary). 2. Make a slightly curved incision from the mastoid process along the anterior border of the sternomastoid to the level of the thyreoid cartilage. 3. Raise the patient's head, tilting the table to an angle of between thirty and forty degrees. 4. Define and retract the sternomastoid. Ligate and divide the common facial vein. Open the carotid sheath at the level of the upper border of the thyreoid cartilage. retract the internal jugular, and apply the clamp to the external carotid at its origin, tightening the clamp until the pulsations of the vessel are controlled. 5. Clear away all visible lymph glands and the submaxillary salivary gland. Ligate the facial vessels. 6. The submaxillary triangle is now empty. Define the posterior belly of the digastric and the posterior margin of the hyoglossus with the styloglossus passing over it. Retract the styloglossus downwards (the hypoglossal nerve is below the operative field), draw the posterior belly of the digastric with the great vessels backwards; if the stylopharyngeus comes into view it is also drawn backwards with the glossopharyngeal nerve. The superior and middle constrictors are now exposed in the floor of the wound. Carry the dissection upwards beneath the jaw, following along the internal pterygoid as far as possible. 7. Dry the wound thoroughly and then pack it with gauze impregnated with vaseline. (If tracheotomy was not done at the beginning of the operation it should now be performed and the pharynx plugged.) 8. Drill the jaw in two places near its lower border just in front of the masseter. Saw through the jaw obliquely. 9. Draw the ascending ramus outwards, cutting the internal lateral ligament if necessary. Define the lingula with the finger, and pass a hook around the inferior dental nerve, draw it from its canal and cut off. If the inferior dental artery is seen it should be secured. 10. Pass a finger into the mouth and place its tip against the anterior margin of the growth. Open the pharynx with scissors in front of the finger. Continue the incision upwards and downwards until its ends are beyond the limits of the growth. Change the glove of the infected hand. Seize the divided edges with forceps and cut backwards from the ends of the incision until the growth can be delivered from the wound; draw it outwards and divide its posterior attachment. This. step might be performed wit hthe galvanocautery, the surface of the tonsil being cauterised as it was.

drawn out. 11. Suture the pharynx with two layers of stout catgut. The edges should be turned in towards the throat. The first layer should be interrupted, commencing at the bottom, the ends of the stitches being left long in order to draw down the upper and more inaccessible parts of the wound. However wide the opening may be an attempt should be made to draw together the edges. This will most likely be possible in the lower part of the wound where the pharyngeal walls are more freely movable. 12. Take out the petrolatum gauze packing and remove the clamp from the carotid. Tie any vessels that may bleed. 13. If any of the muscles of deglutition have been divided in the course of the operation they may now be sutured. Replace the ramus of the jaw and wire it in position. 14. Close the wound, leaving the upper part open for a large drainage tube which must pass down to the pharyngeal suture line and should be packed round with gauze. A smaller tube should be placed in the lower angle of the incision.

The Lipoids By HENRI ISCOVESCO. Trial of a New Therapeutical Method,

By RENÉ DE GAULLAC 3. Have the Misdeeds of Syphilis Been Exaggerated? By R. ROMME.

1. Lipoids.-Iscovesco follows Overton in designating by this name substances which may be extracted from the fluids or the peranchyma of tissue by the solvents of fatty matters, such as ether, chloroform, and benzol. These bodies present marked analogies with fat and form with water colloidal pseudosolutions. They are quite numerous, and the writer proposes to divide them into four groups, the neutral fats, the fatty acids, the soaps, and the lipoids proper. The latter he subdivides into two classes, those which contain phosphorus and those which do not. He then discusses their preparation, their distribution in the organism, and their physicochemical properties.

II. The Surgical Treatment of Exophthalmic Goitre,

By August Hildebrandt.

1. Gangrene of the Skin in Rheumatoid Scarlet Fever.-Hübner reports a rare case of this nature in which the skin over the right elbow joint became gangrenous over a surface, 9 cm. long by 8 cm. broad. He states positively that the gangrene was not due to embolism, but does not explain its occurrence.

6. X Ray Treatment of Seborrhœa Oleosa.-Schmidt finds the results of x ray treatment to be equally good in seborrhœa oleosa as in chronic eczema, lichen simplex chronicus (Vidal), lichen ruber verrucosus, and psoriasis. As both the sebaceous follicles and the sweat glands are apparently more sensitive to the x rays than the hair follicles, no injury of the skin in the form of atrophy or teleangiectasis is to be feared, even when weak irradiations are rendered necessary by a recurrence.

7. The Eberth-Gaffny Bacillus in the Cerebrospinal Fluid of Typhoid Fever Patients.-Silberberg presents the following conclusions: The Eberth bacillus appears to be present in the cerebrospinal fluid of patients with typhoid fever with tolerable frequency. Hence the bacteriological examination of the cerobrospinal fluid furnishes a new diagnostic point in cases of disease suspected to be typhoid fever. The agglutinating properties of the cerebrospinal fluid of typhoid fever patients to the Eberth bacillus is very slight. The bactericide properties of this fluid to this bacillus are much more marked. The physical and chemical properties of the cerobrospinal fluid of typhoid fever patients do not differ from the normal. The withdrawal of a certain quantity of the cerebrospinal fluid from patients suffering from typhoid fever is often of favorable influence on the condition of the patients.

8. Epidemics and Their Management.-Alexander sums up his long paper in the following four conclusions: 1. A well organized board of health is an important aid in the prevention and stamping out of epidemics. 2. All branches of the public board of health must be prepared in times of no epidemic for use when epidemics suddenly appear, and must be entrusted with the incident problems. 3. In like manner during the prevalence of epidemics the preparations of the public board of health must be kept in constant readiness and in touch with other

measures adopted for their control. 4. For the performance of its tasks during the prevalence of an epidemic it is recommended that the official board of health be associated with a medical board.

- The Question of Acute Over Exertion of the Heart,
- Ву Ѕснотт.
- 14. Obituary of Eugen Albrecht Oberndorfer 15. Medical Conditions in Australia, By SCHÜTT.
- 2. Demonstration of Sparse Typhoid Bacilli. -Conradi makes use of the fact that certain analine coloring materials exert a selective antiseptic action to protect the typhoid bacilli, such as malachite green, brilliant green, and picric acid. nutritive media for his cultures are prepared with these with the result that the colonies of typhoid bacilli flourish while concurrent bacteria do not. By this means the presence of typhoid or paratyphus bacilli can be demonstrated within twenty hours even when present in very small numbers.
- 4. Myopia and Its Prevention.—Best ascribes the development of myopia to two factors, near work, and a predisposition caused, it may be, by a faulty elasticity of the chorioid at the posterior pole of the eye, by thinness of the sclera, which in many cases is correlative to the faulty development of the chorioid, which in turn is often correlative with insufficient power of accommodation and convergence, and by the preponderance of the longitudinal portion of the ciliary muscles over the circular. The proportion borne by these two factors in the production of myopia in any given case cannot be readily determined ..
- 10. Pulmonary Stenosis Produced by Traumatism.—Leick reports the case of a young man, twenty years of age, who died of pneumonia. When he entered the hospital he presented the signs of a stenosis of the pulmonary valves in addition to the symptoms referable to the pulmonary condition. Autopsy confirmed the diagnosis of a high degree of stenosis of the pulmonary orifice, and the condition is considered to have been caused in the greatest probability by an accident in which he fell with his full weight on his chest and was rendered unconscious about five years before. From that time the symptoms of pulmonary stenosis were present, though they had never previously appeared.

ZENTRALBLATT FUR INNERE MEDIZIN July 18, 1908.

The Functional Test of the Kidneys by Means of the Salts of Iodine. By H. P. T. OLRUM. Salts of Iodine,

Functional Test of the Kidneys.-Olrum concludes from his studies that kidneys which are in a condition of granular atrophy excrete salts of iodine after a considerable delay (187 hours), while those which are in a state of parenchymatous inflammation, with the exception of the cases of secondary atrophy, show a normal or increased excretion after the administration of the salts. In twelve cases of orthostatic and cyclic albuminuria, the excretion was also increased or normal. It appears that congested kidneys and those in cases of arteriosclerosis without granular atrophy show no excretory change.

ZENTRALBLATT FÜR CHIRURGIE. July 25, 1908.

Antifermentative Treatment of Suppurative Processes By H. KALACZEK without Incision. By L. RENNER. The Treatment of Burns,

Treatment of Burns .- Renner recommends as a dressing for burns of every degree a powder consisting of one part of bismuth subnitrate and two parts of kaolin. The burned area is first thoroughly cleaned, then thickly powdered and bandaged with sterile gauze. The thorough drying of the area and the absence of infection are the chief virtues of the treatment, while the formation of bullæ is almost entirely prevented. The author's results have been most excellent.

ZENTRALBLATT FUR GYNAKOLOGIE July 25, 1908.

I. Nuclear Jaundice of the New Born. By P. ESCH.
2. The "Serpentine" Uterus,
I. Nuclear Jaundice of Infants.—Esch nar-

rates the details of a fatal case of this condition in which the lenticular nucleus was found deeply icteric. The jaundice was also found intense in the striæ, in the floor of the aqueduct, and through the ependyma, the nuclei of the vagus and of the acoustic nerve could be seen deeply stained. The clinical picture of this disease has not been worked out. In the author's case and those of Schmorl and Beneke, the infant became intensely jaundiced early in life, very soon presented bulbar symptoms, and died in convulsions with tonic contractions of the extremities and muscles of the back. The diagnosis can only be occasionally made, while the prognosis appears to be uniformly fatal. The author utters a warning against regarding cases of icterus neonatorum as not being dangerous, especially when combined with convulsions and when occurring in premature and weak infants.

Broceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY Meeting of April 3, 1908 DR. CHARLES H. PECK in the Chair.

Hernia of the Lung.—Dr. Edward Adams presented a patient with hernia of the lung. The first case of this nature, he said, was reported in 1499.

since which time but forty-eight cases had been recorded. These forty-eight cases were classified as follows: Congenital, ten; spontaneous, eight; traumatic, thirty. During the civil war there were about 20,000 injuries to the chest wall, and among these were found but five cases of hernia of the lung. During the Russo-Japanese war not one case was recorded.

The patient shown was twenty-two years old, an iron worker in Buenos Aires. Two years ago, when lifting a heavy piece of iron, he felt something give way in his chest and soon noticed a bulging in the upper intercostal spaces. This was accompanied by pain. On inspection, there was found nothing except a slight bulging in the second and third intercostal spaces on the right side and near the median line; this bulging was more marked when he bent forward than when he was in the erect posture. Upon palpation, the swelling was found to be soft and elastic and not adherent to the skin. On percussion, it was found to be tympanitic. On auscultation, there was a slight exaggeration of the breath sounds with an increased vocal fremitus. The diagnosis was to be made from aneurysm, empyema, abscess of the lung, angeioma, lipoma, cyst, and cold abscess. An x ray picture showed nothing. Aspiration of the swelling gave negative results. The treatment consisted in a well fitting pad held in place by straps. If a cure was not effected in a short time, he intended to cut directly down and mattress suture the muscles with silver wire.

Dr. WILLIAM HENRY LUCKETT questioned the diagnosis. The patient could not produce this tume-faction while in the erect posture; if this was a heriai, he could produce it in whatever position he assumed. The tumor did not crepitate under the finger or on auscultation. He thought that it possibly might be a peculiar sacculation, possibly containing fluid. There might be a small opening, with a sac inside as well as outside the chest wall, a wallet shaped affair.

Dr. H. A. HAUBOLD believed the tumor was too near the median line to be a hernia of the lung. If the patient made a sudden exertion or took a deep inspiration, the lung would be driven toward the diaphragm, where there was room for it. He suggested that it might be a branchial cyst.

Dr. A. V. Moscowitz said he had carefully examined the tumor some time before, and believed it to be a hernia of the lung. He had seen one other such a case, and this presented similar symptoms.

Dr. WILLY MEYER had seen and examined the patient several weeks before and believed in Dr. Adams's diagnosis. The man got his hernia by lifting a heavy weight. The percussion sounds were those of lung, and readily made out. With increased intrathoracic pressure there was increase in the size of the swelling.

Dr. CHARLES A. ELSBERG called attention to the fact that, when the patient inspired, the skin over the tumor sank in, and when he expired it bulged out. He thought it might be a hernia of the pleura, the sac containing no lung, and formed by the parietal pleura.

Dr. Adams said that the physical signs pointed to hernia of the lung and to nothing else.

Perforating Gastric Ulcer; Gastroenterostomy. Dr. Whiteam C. Le & presented this patient.

Two weeks before his admission to the hospital he had been having pain after eating. One morning, about 9 o'clock, he was seized with sudden pain in the abdomen, which was followed by vomiting. Dr. Lusk saw him at 5 p. m. and found the abdomen rigid and tender, particularly over the region of the appendix, and to a less degree over the pit of the stomach. Fourteen hours after the onset of the attack an operation was performed. At the point of incision a pint and a half of pus gushed out. The appendix was found to be normal. Another incision was made above, and a small perforation was revealed in the anterior wall of the stomach at the upper portion, near the pylorus. There were adhesions around the gallbladder; the gallbladder was adherent over the entire front of the pylorus. The perforation was closed with three rows of chromic sutures uniting the gallbladder to the stomach and finally drawing a piece of fat from above and one from below together, over the line of union. A posterior gastroenterostomy, leaving no slack in the loop of the jejunum, was performed by suture. No irrigation was employed. There was little sponging, and the bulk of the pus was removed with large gauze pads tucked down into the pelvis. Proper drainage was used. The temperature promptly dropped, and the patient made an uninterrupted recovery.

Dr. Lusk called attention to some experiments on dogs by Fibich. Gastric ulcers were produced artificially. It was found that with no gastroenterostomy such ulcers remained unhealed as long as three weeks, whereas, when gastroenterostomy was performed at various intervals of time following the production of the ulcer, healing occurred within three or four days: The pulse in the case reported was no indication of the patient's real condition. The diagnosis was practically made on the physical signs, together with corroborative blood findings.

Bier's Hyperæmic Treatment. - Dr. WILLY MEYER believed that Bier's hyperæmic treatment was the best method of achieving certain results. Bier started his artificial hyperæmia in the treatment of surgical tuberculosis. He then read that pathologists had seen that patients with chronic hyperæmia of the lungs due to valvular heart disease would not be stricken with tuberculosis. On the other hand, a patient with stenosis of the pulmonary artery was apt to be stricken with tuberculosis. And on the basis of this Bier started his surgical investigations in 1892, and he and his followers had since shown results. Artificial hyperæmia was a powerful agent, rich in therapeutic results. Formerly physicians worked with remedies on a chemical basis; now, in addition, on a physical one. The profession now were only beginning to understand its value. He felt sure that as physicians knew more and more about it they would appreciate its value more and more. In Bier's hyperæmic treatment, instead of fighting the symptoms of inflammation, the point was to increase them by means of an increased amount of blood. To accomplish this they applied to the extremities an elastic bandage, to the head an elastic band, to the shoulders or testicles an elastic tube, etc. Over other inflamed regions of the body a glass apparatus was applied, which was as useful as the elastic bands. Eleven patients were presented by Dr. Meyer to show the results of the Dr. James Morley Hitzrot had usually got bad results in streptococcic infections of the superficial variety.

Dr. Lyle had used this treatment with success

and was very enthusiastic over it.

Dr. MEYER advocated long incisions in infections of the tendinous sheaths in osteomyelitis, etc., before applying the Bier treatment. The incision took care of the pus; artificial hyperæmia, of the inflammation. He then demonstrated the Kuhn mask for the production of artificial hyperæmia of the lungs.

Pneumothorax and Posture; the Importance of the Abdominal Position in Operations upon the Pleura and Lungs .- Dr. CHARLES A. ELSBERG read this paper. The dangers from the sudden entrance of air into the normal pleural cavity had impeded the progress of intrathoracic surgery, and much experimental work had hence to be done to discover means whereby we might guard against and overcome the dangerous respiratory embarrassment which was apt to ensue when the normal pleural cavity was invaded. Adhesions between the visceral and parietal layers of the pleura were, fortunately, present in from fifty to seventy-five per cent. of the cases with an inflammatory process; but, unfortunately, there were no known physical signs which enabled us to say whether or not such adhesions were present. Delagenière had pointed out that one could often prevent the occurrence of serious symptoms from the sudden collapse of the lung by quickly grasping the lung, drawing it into the wound, and fixing it there by sutures. The greatest advance in the surgery of the thorax had been made by Sauerbruch and Brauer, of Germany, with their cabinet and other apparatus, but they had been adopted by a very few, because of the great expense entailed.

During the past year Dr. Elsberg had done some experimental work on dogs in the Department of Physiology and Pharmacology at the Rockefeller In-If a small opening was made in the right or left pleura of a dog that was lying on the back, or on the right or left side, the animal would, in most instances, continue to breathe well, although the amount of inspired or expired air would be less than the normal. But such an animal was very sensitive to the slightest influence which disturbed the breathing, producing a typical pneumothorax dyspnœa. In almost all the animals in which the size of the opening approached or exceeded that of the trachea, dyspnæa and death followed, regardless of what part of the chest was opened. When, however, the animal was operated upon while lying flat upon its belly, not only could a small opening be made and the animal continue to breathe normally, but even a very large opening could be made and the breathing continue regularly and quietly; even one half the chest wall could be removed and the animal survive. Again, if a dog on its back with an opening in the chest, with typical violent dyspnæa due to the pneumothorax, was turned on its belly, the breathing would become regular and quiet again, and the pressure of air breathed in and out would be found to be several times as great as when the animal was on its back. On the other hand, a dog on its belly, with a large opening in one pleural cavity and breathing quietly, could be brought into a condition of grave dyspnœa and asphyxia by turning it on its back. These experiments seemed to show that, in dogs at

least, pneumothorax was better borne when the animal was on its belly than when it was in any other posture. It was also shown that pneumothorax was much better borne when the animal was deeply under the influence of an anæsthetic.

Dr. Elsberg had applied these results in his work at the Mt. Sinai Hospital. All the patients on whom operations were performed which required the opening of the pleura were operated upon while lying flat on the abdomen. He had operated upon a large number of patients with empyema, upon two with abscess of the liver, upon three with subphrenic abscess, and upon one with bronchiectatic cavity in the left lung. In all these the pleura was opened. The patients in whom a normal pleura had to be opened showed few untoward symptoms when the opening was made and air was allowed to enter the pleural cavity. In the patients in whom an operation for empyema was done, it was noted that with only one exception the coughing and interference with breathing that were regularly observed when the opening in the pleura was made for this affection, were entirely absent. He hoped that the abdominal posture in pleural and pulmonary operations would be tried by others

Arthritis Deformans of the Hip; a Preliminary Report of a New Operation .- Dr. FRED H. ALBEE read this paper. Arthritis deformans of the hip, he said, attacked young and middle aged adults as well as the aged. This condition had been known by many names, the most common being coxitis senilis, which was misleading and not appropriate. The true cause of this affection was still obscure. He believed that old age played a small part. The site of origin in arthritis deformans was still a disputed point, although recent authorities were inclined to consider it among the arthropathies of spinal origin. In the early stages of this disease the joint fluid was increased; later it was diminished. Changes in the cartilage were noted early, and the articular surfaces became thinned and finally disappeared entire-The head of the bone thus laid bare became smooth, polished, and eburnated. Marginal ecchondrosis or osteophytes appeared; they might become detached and appear as loose bodies in the joint. The acetabulum was deepened. The head of the femur wore away more and more, and the marginal outgrowths progressed toward the trochanter. neck of the femur hypertrophied and might bend, becoming more at a right angle with the shaft than normal. There was a consequent shortening of the leg. There were increasing adduction and flexion with permanent contracture or ankylosis. The disease began with pain in and about the joint. Muscular atrophy came on early. The arc of motion gradually diminished, until finally the joint becomes stiff. The amount of pain and effusion varied greatly. A very important diagnostic point was that, if motion existed in the advanced cases, it would be practically in one plane and in that of flexion. The earliest limitation of motion was in abduction and rotation. The acute form might simulate sciatica, articular rheumatism, gonorrhœal arthritis, infectious arthritis, and tuberculous hip disease. treatment was, first, to relieve the pain, and, secondly, to correct the deformity. The local treatment was more important than the general. Further traumatism should be prevented by protecting the joint.

Rest in bed with a traction apparatus if necessary would do much toward relieving discomfort. After the pain and joint irritability had been controlled, the patient was allowed to go about with a spica, with or without crutches; this enabled him to enjoy fresh air and mild exercise. Other therapeutic measures should be regarded as only accessories. A certain number of progressive and very advanced cases associated with marked deformity and disability demanded operative treatment. Those procedures which terminated in ankylosis had been observed to be the most successful, in respect to both comfort and efficiency.

Dr. Albee then gave the history of a patient, fiftynine years old, with advanced arthritis deformans of the right hip. The brace treatment was recommended and declined. Eleven months ago the patient came to him and asked if something could not be done for him. He was a powerfully built man, weighed 185 pounds, and walked with a marked limp. The right shoe was built up two inches and a half. The actual bony shortening was a quarter of an inch; the practical shortening two inches and three quarters. The leg was much atrophied and decidedly adducted and flexed. Attempts at passive motion were painful. A skiagraph showed the head of the femur much worn away and flattened, with many bony outgrowths about the rim of the acetabu-111111

In view of the disintegration of the joint, the great adduction and flexion, with firm contractures. in so large and powerfully built a man, with the leg in faulty position, with progression toward bony ankylosis, it seemed best to aim for immediate firm ankylosis with the limb in a position of slight overcorrection of the deformity to compensate for the existing practical shortening. Therefore, the operative indications were to devise a procedure which would, if possible, fulfil these requirements and at the same time produce of itself as little real bony shortening as possible.

The hip joint was reached by an anterior incision five inches long, starting from just below and to the inner side of the anterior superior spine of the ilium, and extending downward along the inner border of the sartorius muscle, which was retracted outward. The muscles and the deep structures were separated by blunt dissection, and the iliacus and the rectus femoris muscles were retracted inward. A part of the large ring of osteophytes about the rim of the acetabulum were turned upward with the soft tissues adherent to them. It was thought wise to leave as many as feasible, on account of their bone forming possibilities. In so thick a thigh, with the presence of so much bony outgrowth, it required some care to ascertain definitely the situation of the joint and head. With the head of the bone in situ, about one half of its upper hemisphere was removed with a large chisel through a plane at right angles to the long axis of the shaft of the femur. Then with the same instrument the acetabulum was transformed into a flat surfaced roof, against which the fresh surface of the head was finally brought into firm contact by abduction of the thigh. Upon further attempting abduction, it was found impossible, on account of the shortened adductors. An open division of these tendons and muscles was found necessary before the leg could be brought into proper position. The plain surfaces of the head and acetabulum were then brought together by simply abducting the thigh, and the capsule and soft tissues were then sutured. The leg was put up in a spica from axilla to toes in

strong abduction.

This operation had the following advantages: First, it assured a bony union, bringing two large bony surfaces together for ankylosis, and held them firmly by the mere correction of the deformity. Secondly, it produced a minimum amount of bony shortening. The patient made an uneventful convalescence and was walking with crutches at the end of four weeks. At the end of nine weeks he walked without cane or crutch and went back to his work as patrolman in four months. He had not suffered any pain since the operation, and the leg had remained in the corrected position. He had continued as a patrolman, working nine hours a day, and had not lost a day on account of his hip.

Dr. Albee had done this operation five times; all the cases were advanced ones of arthritis deformans. The ages of the patients were respectively thirty, sixty, sixty-three, fifty-five, and sixty-seven. shock was very slight in every case. This he believed was accounted for by the facts that the hip was not disarticulated and that there were very few structures cut, and all had healed by first intention. The results in all the cases were most favorable.

Xetters to the Editors.

STATE EXAMINATIONS.

SPRINGFIELD, ILL., August 18, 1908.

To the Editors:

The State of Illinois is the "great State" mentioned in your editorial of August 1st, under the heading of State Examinations, and the "chemistry paper" criticised by Dr. Willis G. Tucker, professor of chemistry in the Albany Medical College, is the chemistry paper presented by the Illinois State Board of Health to candidates at the examination on October 23-25, 1907. Unlike the editors, I do not agree with Dr. Tucker in his strictures, and I fail to find justification for the editors' assertion that the "average State examination is no trustworthy criterion of a candidate's title to the license to practise medicine.

Permit me to briefly discuss Dr. Tucker's criticisms on the questions under consideration. It may be unjustifiable to give so much weight to a matter like valency (question No. 1) in a medical examination. But Dr. Tucker will find that this is not the consensus of teachers in medical chemistry. Questions relating to valence are often given in medical examinations. These questions are doubtless deemed of importance, but, important or unimportant, it may be said that question No. 1 and the other questions discussed by Dr. Tucker compare very favorably with some of the questions in chemistry "set at a recent examination (October 1-3, 1907) of a great State," a State which was once a province of the Netherlands. It may be asked why Dr. Tucker has not seen fit to criticise these questions, which certainly have been brought to his attention. Parenthetically, it was not necessary for Dr. Tucker to cross the Alleghenies in

order to obtain material for criticism, assuming that

criticism was called for.

By an act of interpolation Dr. Tucker questions the propriety of the term "formula" in questions 3 and 5. As Dr. Tucker should know, this term is proper, as is its analogue "equation," which appears in the following question recently submitted by the examining board of the Netherland province: "Complete the following equation: 2KI+MnO2+2H-SO4=." Surely Dr. Tucker must be at a loss for words when he attempts to discredit the ability of a State examiner to formulate questions in a proper manner.

It will be of interest to the editors and the readers of the *Journal* that questions I, 2, 3, and 4, which have occasioned Dr. Tucker such perturbation, questions which he deems "incompetent, immaterial, and irrelevant," were taken from the IgoI edition of Remsen's *College Chemistry*, a textbook recommended and used in the leading medical col-

leges of the United States!

In referring to question No. 5. Dr. Tucker, who assures us that he has been teaching chemistry for over thirty years, says: "The last question assumes the existence of an oxide of potassium that I never heard of and which has. I believe, no existence." For the information of Dr. Tucker I will say that question No. 5 affirms the existence of an oxide of potassium which certainly has an existence. K₂O₂, the oxide of potassium in question, is formed by heating potassium in a limited supply of nitrous oxide.

In conclusion, Dr. Tucker says: "I doubt whether one member in ten on our State boards, save perhaps the examiners in chemistry, could get forty per cent. on such a paper as this." I hardly think that Dr. Tucker is competent to pass on the qualifications of the members of the different State boards from Maine to California, but, waiving this, it must be recalled that the questions under consideration . were submitted to students, and we are concerned alone—at the present time at least—with the ability of the students to answer these questions. It will certainly be of interest to the readers of the New York Medical Journal that, out of the fifty-two candidates who took the examination of the Illinois State Board of Health on October 23-25, 1907, thirty-eight received averages varying from seventy-five per cent. to ninety-one per cent. in the examination on chemistry.

It is so easy to criticise examination questions, and, as Dr. Tucker must know, it is difficult for examiners to prepare acceptable questions for six examinations yearly.

JAMES A. EGAN,

Secretary, Illinois State Board of Health.

A CORSET FOR GASTROPTOSIS.

126 EAST THIRTY-FOURTH STREET.
NEW YORK, August 18, 1008

To the Editors:

Dr. Anthony Bassler, in his article under this title, published in your esteemed *Journal* of July 18th, passes some remarks on my plaster belt which remind me of what I have read in the history of novelties in medicine. Better men than myself, Semmelweis for instance, have complained that their new methods were discredited by many who had

applied them with disregard to the directions given by the inventor. The disadvantages described by Dr. Bassler are due to unskilful application of the plaster. True it is that some patients' skin is too irritable to bear the plaster, but these are exceptional cases, very rare exceptions. Most patients speak with enthusiasm of the comfort and benefit they experience while wearing the belt, and they wear it for five weeks and sometimes much longer. They are not deprived of bathing while the appliance is on. As a matter of course some experience is required to apply it properly and to see that it is kept on properly.

CARSICKNESS.

GLOVERSVILLE, N. Y., August 22, 1908

To the Editors:

I read the article on carsickness, by Dr. Wile, with much interest, as I have treated many cases this last five years. I attribute the cause to the nystagmus produced by looking out of the car windows. Look out of a car window and observe how rapidly the telegraph poles flit by; each one is seen and involuntarily followed by the eye until it is opposite, when the eye shifts to the one following. This is true of near buildings; objects farther away seem to move slower, and those very far off seem to be almost stationary, until the whole landscape appears to be revolving round a common centre. The unconscious effort to take in everything produces a rapid lateral oscillation of the eyeballs, as any one can observe by watching the eyes of his fellow passengers. The eye strain is enormous, and is the chief factor in producing carsickness. This can be proved by asking a patient who is subject to carsickness to look steadily at a mirror which is moved rapidly to and fro or tilted backward and forward. He will immediately complain of nausea and vertigo.

The treatment consists in advising the patient to avoid looking out of the car windows and in giving him a grain of citrate of caffeine shortly before he takes the cars, and repeating it every hour as long as there is any tendency to be sick. I have been able by these means to relieve many sufferers.

WILLIAM CLARK WOOD.

CRIMINAL ABORTION.

282 SOUTH MARSHFIELD AVENUE, CHICAGO, August 1, 1908.

To the Editors:

I have read the very interesting editorial in the New York Medical Journal of July 25th, entitled Medical Men as Detectives and Prosecutors. The question of abortion is a very delicate one, for is not the law against bigamy an abortion by itself? However, there is hope coming from the speech of Dr. Walter B. Dorsett on the subject of Criminal Abortion in Its Broadest Sense, before the meeting of the American Medical Association in Chicago last June, of which an abstract appeared in the New York Medical Journal. Dr. Dorsett called attention to the fact that the laws were insufficient or inadequate, and he advised the appointment of a committee by the House of Delegates, to be known as

the Committee on Criminal Abortion, which should undertake to secure the passage of suitable laws after having studied the conditions from all points L. M. Young. of view.

Book Antices.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Pharmacology. The Action and Uses of Drugs. By MAURICE VEJUX TYRODE, M. D., Instructor of Pharmacology in the Medical School of Harvard University. Philadelphia: P. Blakiston's Son & Co., 1908. Pp. ix-255. (Price, \$1.50.)

This little book has been prepared on an excellent plan, drugs being grouped according to their principal therapeutic actions and each group designated by the name of the most prominent drug contained in it. Thus, we have the group of morphine, the group of quinine, etc. Of course, the information given is necessarily condensed, but the work does not purport to be exhaustive. A somewhat remarkable statement appears in the section on ivy poisoning. "The penis and testicles of the man," says the author, "may be swollen to a size such as to approach in appearance the organs of a bull." This may do well enough for the testicles (that is, the scrotum), but as for the penis, when we call to mind the nerf de bœuf the comparison loses force.

At the close of the consideration of almost every group of drugs there is a section, entitled Materia Medica, giving official and commercial titles of the drugs and their preparations. As regards the pharmacopœial names, these lists are inexcusably erroneous. The punctuation used in the book is for the most part unintelligible to us, and here and there we find indications that the author has but a defective knowledge of the English language. These faults, however, may easily be corrected in the next edition.

Physiotherapie. Mécanothérapie — rééducation — sports — méthode de Bier—hydrothérapie. Par les Docteurs Fraikin, Grenier de Cardenal, Constensoux, Tissié, Delagenière, Pariset. Avec 114 figures dans le texte. Paris: J. B. Baillière et Fils. 1909. Pp. xii-404.

This little book is one of twenty-four volumes published under the general title of Bibliothèque de thérapeutique, under the direction of Dr. A. Gilbert and Dr. P. Carnot, who are respectively professor and adjunct professor of therapeutics in the Paris Faculty of Medicine. The part on mechanotherapy is by Fraikin and Grenier de Cardenal, who give a list of sixty different forms of apparatus for the production of passive exercise, vibration, etc. It is hardly necessary to say that the individual practitioner will not generally be willing to invest in such an armamentarium. Some of our great hospitals are possessed of much the same array, and it seems to be expected by the authors that physicians in general will send to those who are proficient in machine therapeutics such patients as they judge to be in need of elaborate mechanical treatment.

The section on motor reeducation is by Constensoux. It is an interesting exposition of the subject. Tissié deals with games and sports from the therapeutic point of view. Foot ball, says the author, is the best means, at least in France, employed in the struggle against alcoholism. Delagenière writes of Bier's passive hyperæmia, which he thinks appropriate for a multitude of morbid conditions. Hydrotherapeutics is treated of by Pariset. It occupies about half the book. The section is fairly comprehensive.

It is unusual to find in a French book so good an index as the one with which this is provided. It

is followed by the table of contents.

Lehrbuch der Chirurgie. Bearbeitet von Prof. Klapp, Berlin; Prof. Küttner. Breslau; Prof. Lange, München; Prof. Lange, Amsterdam; Prof. Pave, Greifswald; Prof. Perthes, Leipzig; Prof. Poppert, Giessen; Prof. Preysing, Cöln; Prof. De Quervain, Bern—La Chaux-de-Fonds; Prof. J. Riedinger, Würzburg; Prof. Roysing, Kopenhagen; Privatdozent Dr. Sauerbruch, Marburg; Prof. Schloffer, Innsbruck; Prof. Tillmann, Cöln; Prof. Wilms, Basel; Prof. Wullstein, Halle a. S., und Prof. Wilms, Basel. Erster Band; allgemeiner Teil. Chirurgie des Kopfes, des Halses, der Brust und der Wirbelsäule. Mit 326 zum Teil mehrfarbigen Abbildungen. Jena: Gustav Fischer, 1008. Pp. xii-600. (Price: paper, 10 M.; bound, 11 M.)

For a variorum work, this is to be one of verv

For a variorum work, this is to be one of very moderate bulk, for it seems that there are to be only two volumes in all. It appears to be on a par with a number of other treatises on surgery of the present day-not distinguished for any great degree of excellence, though quite sufficient for the ordinary

needs of the student and practitioner.

The illustrations are well executed, but we think the impressions would have been clear enough without the use of highly glazed paper, which runs all through the volume. The typography is excellent, but the binding is execrable—the sheets break loose under the slight strain incident to cutting the leaves.

Die nervösen Erkrankungen des Geschmackes und Geruches. Von Prof. L. v. Frankli-Hochwart. Zweite, gänzlich umgearbeitet Auflage. Mit 14 Abbildungen. Wien und Leipzig: Alfred Hölder, 1908. Pp. lv-96.

The first edition of Frankl-Hochwart's small monograph has been amplified, revised, and in large part rewritten. It now contains about a hundred pages. In the first portion he discusses the physiology of taste, the nervous mechanism underlying the function of taste, methods of testing, and the pathological modifications, such as the ageusiæ, hyperalgesia gustatoria, and parageusiæ. Special stress is laid upon the taste modifications as found in lesions of the spinal cord, in ear disorders, facial palsy, glossopharyngeal disturbances, bulbar lesions, tabes, multiple sclerosis, syringomyelia, leprosy, hysteria, epilepsy, and mental diseases.

The second part of the book discusses the physiology and nervous mechanism of smell and its pathological modifications. Anosmia, hyperosmia, and parosmia are in turn taken up and these diseased or perverted conditions thoroughly analyzed.

This monograph is practically the only one of its kind in which the results of modern methods of research in these subjects have been embodied. It is clearly written, comprehensive, and thoroughly trustworthy.

BOOKS, PAMPHLETS, ETC., RECEIVED

Transactions of the New Hampshire Medical Society at the One Hundred and Seventeenth Anniversary, held at Concord, May 14 and 15, 1008 Pp. 332 Manual of Psychiatry. By J. Rogues de Fursac, M. D.,

Formerly Chief of Clinic at the Medical Faculty of Paris,

Formerly Chief of Clinic at the Medical Faculty of Paris, Physician in Chief of the Public Insane Asylums of the Seine Department. Authorized Translation from the French by A. J. Rosanoff, M. D., Second Assistant Physician, Kings Park State Hospital, N. Y. Second American from the Second French Edition. Revised and Enlarged. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1908. Pp. ix-406.

The Principles and Practice of Gynæcology for Students and Practitioners. By E. C. Dudley, A. M., M. D., Ex-President of the American Gynæcological Society, Professor of Gynæcology, Northwestern University Medical School, etc. Fifth Edition, Revised and Enlarged. With Four Hundred and Thirty-one Illustrations and Twenty Full Plates in Colors and Monochrome. Philadelphia and New York: Lea & Febiger, 1908. Pp. 806.

Cholécysto-pancréatite. Essai de pathogénie. Par le Docteur Reine Maugeret, ancien interne des Hôpitaux de Paris. Paris: G. Steinheil, 1908. Pp. 150.

Chronischer Magenkatarrh (Gastritis chronica). Von Hofrat Dr. Friedrich Crämer. Mit 4 Kunstdruck-Tafeln. München: J. F. Lehmann, 1908. Pp. iv-168.

Pathological Technique. A Practical Manual for Workers in Pathological Histology and Bacteriology, Including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By Frank Burr Mallory, A. M., M. D., Associate Professor of Pathology, Harvard University Medical School, First Assistant Visiting Pathological Laboratory of the Massachusetts General Hospital; Assistant Professor of Pathology, Harvard University Medical School, Fourth Edition, Revised and Enlarged, with 152 Illustrations. Philadelphia and London: W. B. Saunders Company, 1908. Pp. 480. (Price, §3.)

Index of 1,180 Post Mortems of the Insane, Norristown, Pa. By H. J. Sommer, Jr., M. D., Pathologist; Formerly Assistant Physician of the Institution. With an Introduction by Allen J. Smith, A. M., M. D., Professor of Pathology, Univerity of Pennsylvania; Consulting Pathologist of the Hospital, etc. 1918.

Miscellany.

Prizes Offered by the International Congress on Tuberculosis.-The Central Committee of the International Congress on Tuberculosis at Washington has announced the following prizes: I, A prize of \$1,000 for the best evidence of effective work in the prevention or relief of tuberculosis by a voluntary association since the first International Congress in 1905. 2, A prize of \$1,000 for the best exhibit of an existing sanatorium for the treatment of curable cases of tuberculosis among the working classes. 3, A prize of \$1,000 for the best exhibit of a furnished house for a group of families of the working class, designed in the interest of the crusade against tuberculosis. 4, A prize of \$1,000 for the best exhibit of a dispensary or kindred institution for the treatment of the tuberculosis poor. 5, A prize of \$1,000 for the best exhibit of a hospital for the treatment of advanced pulmonary tuberculosis. 6, The Hodgins Fund prize of \$1,500 is offered by the Smithsonian Institution for the best treatise that may be submitted on The Relation of Atmospheric Air to Tuberculosis. 7, A prize of \$100 is offered for the best educational leaflet submitted in each of the seven classes defined below: (A) For adults generally (not to exceed one thousand words). (B) For teachers (not to exceed two thousand words). (C) For mothers (not to exceed one thousand words). (D) For indoor workers (not to exceed one thousand words). (E) For dairy

farmers (not to exceed one thousand words). (F) For school children in grammar school grades (not to exceed five hundred words). (G) Pictorial booklet for school children in primary grades and for the nursery. 8, A gold medal and two silver medals are offered for the best exhibits sent in by any State of the United States illustrating effective organization for the restriction of tuberculosis. 9, A gold medal and two silver medals are offered for the best exhibits sent in by any State or country (the United States included) illustrating effective organization for the restriction of tuberculosis. 10, A gold medal and two silver medals are offered for each of the following exhibits: (A) For the best contribution to the pathological exhibit. (B) For the best exhibit of laws and ordinances in force June 1, 1908, for the prevention of tuberculosis by any State of the United States. (C) For the best exhibit of laws and ordinances in force June 1, 1908, for the prevention of tuberculosis by any State or country (the United States excluded). (D) For the best exhibit of laws and ordinances in force June 1, 1908, for the prevention of tuberculosis by any municipality in the world. (E) For the society engaged in the crusade against tuberculosis having the largest membership in relation to population. (F) For the plans which have been proved best for raising money for the crusade against tuberculosis. (G) For the best exhibit of a passenger railway car in the interest of the crusade against tuberculosis: (H) For the best plans for employment for arrested cases of tuberculosis. 11, Prizes of two gold medals and three silver medals will be awarded for the best exhibit of a workshop or factory in the interest of the crusade against tuberculosis. The following constitute the committee on prizes: Dr. Charles J. Hatfield, Philadelphia, chairman; Dr. Thomas G. Ashton, Philadelphia, secretary; Dr. Edward R. Baldwin, Saranac Lake; Dr. Sherman G. Bonney, Denver; Dr. John L. Dawson, Charleston, S. C.; Dr. H. B. Favill, Chicago; Dr. John B. Hawes, 2d, Boston; Dr. H. D. Holton, Brattleboro; Dr. E. C. Levy, Richmond, Va.; Dr. Charles L. Minor, Asheville, N. C.; Dr. Estes Nichols, Augusta, Me.; Dr. M. J. Rosenau, Washington; Dr. J. Madison Taylor, Philadelphia; Dr. William S. Thayer, Baltimore; Dr. Louis M. Warfield, St. Louis.

Army Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Army for the week ending August 20, 1908.

BAKER, CHARLES L., First Lieutenant. Recently appointed from contract surgeon, with rank from July 7, 1908; ordered to active duty in the service of the United States, and assigned to duty at present station.

BLANCHARD, R. M., Captain. Leave of absence extended one month

BLOOMBERGH, H. D., Captain. Granted twenty days of absence, to take effect about October 5, 1908.

Brown, O. G., Captain. Granted ten days' leave of absence. FIELD, PETER C., Captain. Ordered to proceed to Fort Benjamin Harrison, Indiana, for duty during the

GRIFFS, FRANK C., First Lieutenant. Order for duty at camp of instructions, Fort Benjamin Harrison, Indi-

ana, revoked.

HALLIDAY, FRANCIS A., First Lieutenant. Ordered to re-port in person to Colonel Valery Harvard, president of the board of officers appointed to meet at the Army Medical Museum Building, Washington, D. C for examination to determine fitness for appointment as first lieutenant in the Medical Corps of the Army.

HASSELTINE, H. E., First Lieutenant. Granted two months' leave of absence.

HENNING, O. F., First Lieutenant. Ordered to accompany

the command at Fort Sheridan, Ill., to camp of instruc-tion, Fort Benjamin Harrison, Ind.

Kirkpatrick, Thomas J., Major. Leave of absence ex-

tended fourteen days.
McCown, Thomas B., First Lieutenant. Assigned to ac-

THOOWN, THOMAS B., FIRST Delicement. Assigned to active duty at present station.

SHORTLINGE, E. D., Captain. Resignation of commission as a medical officer of the Army has been accepted by the President, to take effect September 15, 1908.

SNODDY, CARY A., Captain. Honorably discharged from the services of the United States.

Tyler, George Trotter, First Lieutenant. Ordered to proceed from Fort Monroe, Virginia, to Fort Fremont,

S. C., for temporary duty.
WEED, FRANK W., Captain. Granted leave of absence for thirty days.

Navy Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Navy for the week ending August 29, 1908:

BIELLO, J. A., Assistant Surgeon. Detached from duty with

the Pacific Torpedo Fleet, and ordered to the Naval Hospital, Mare Island, Cal. Brooke, F. H., Assistant Surgeon. Detached from the Montgomery and ordered to the Naval Hospital, Bos-

ton, Mass.

Brown, E. M., Passed Assistant Surgeon. Unexpired portion of sick leave revoked; ordered to the naval recruiting station, Los Angeles, Cal.

BUNKER, C. W. O., Assistant Surgeon. Detached from the

Arkansas and ordered to the Montgomer

DUHIGG, J. T., Assistant Surgeon. Detached from the naval recruiting station, Los Angeles, Cal., and ordered to duty with the Pacific Torpedo Fleet.

HATHAWAY, G. S., Assistant Surgeon. Detached from the Naval Hospital, Boston, Mass., and ordered to Washington, D. C., September 1st, for examination for promotion and these to await coders. motion, and then to await orders. HOEN, W. S., Passed Assistant Surgeon. Ordered to duty

with flotilla of lighthouse vessels en route to the Pacific Coast.

LANE, H. H., Assistant Surgeon. Detached from duty the Department of Government and Sanitation, Isthmian Canal Zone, Panama, and ordered to take a course of instruction at the Naval Medical School, Washington, D. C., October 1st.

McClurg, W. A., Medical Director. Detached from duty

as a member of the naval examining and naval medical examining boards, Washington, D. C., September 1st,

and ordered home.

McLean, N. T., Passed Assistant Surgeon. portion of leave revoked; detached from the naval sta-

tion, New Orleans, La., and ordered to the Dolphin. Murphy, J. A., Surgeon. Detached from the Dolphin and

ordered home to await orders.

Sellers, F. E., Assistant Surgeon. Detached from the Nevada, and ordered to the Texas, when commissioned Steele, J. M., Medical Inspector. Detached from the navy yard Portsmouth. N. H., September 18th, and ordered home

TURNER, H. W. B., Assistant Surgeon. Ordered to the Naval Medical School Hospital, Washington, D. C., for

Births, Marriages, and Deaths.

Married.

JANSS-BRALY.-In San Francisco, on Wednesday. August 19th, Dr. Herman Janss and Miss Emma Braly, of Los Angeles.

KATZOFF—FERMAN.—In Lancaster, Pennsylvania, on Wednesday, August 19th, Dr. Solomen C. Katzoff and Miss Yetta W. Ferman.

EICHBERG.—In Big Tupper Lake, New York, on Tuesday, August 18th, Dr. Joseph Eichberg, of Cincinnati, aged fortynine years.

HAMME.—In Cottonwood Falls, Kansas, on Wednesday,

August 26th, Dr. J. M. Hamme.

Millspaugh.—In Richmond, Staten Island, on Thursday,
August 27th, Dr. Isaac L. Millspaugh, aged eighty-one

Moore.—In New Hope, Kentucky, on Friday, August 21st, Dr. J. S. Moore.

Russell.-In Owensboro, Kentucky, on Saturday, August

22d, Dr. J. D. Russell, aged sixty-two years.
Tobey.—In Huntsville, Canada, on Tuesday, August 18th,
Dr. Henry A. Tobey, of Toledo, Ohio, aged fifty-six years.
URIAN.—In Penllyn, Pennsylvania, on Thursday, August 27th, Dr. Harry Drain Urian, of Philadelphia, aged fortyone years.

WHITEHEAD.—In Elizabeth, New Jersey, on Thursday, August 20th, Dr. Rufes B Whitehead, aged thirty-six years.

EXPLANATION OF SEEMING PARADOXES IN MODERN PHTHISIOTHERAPY.

With Particular Reference to Sun, Air, Water, and Food as Remedial Agents.*

By S. Adolphus Knopf, M. D., New York,

Professor of Phthisiotherapy at the Postgraduate Medical School and Hospital; Associate Director of the New York Health Department Clinics for Pulmonary Diseases; Visiting Physician to the Riverside Sanatorium for Consumptives, etc.

Whenever any theory is advanced for treatment or prevention of disease different from the habitual therapeutic methods, there will almost invariably arise more or less heated discussions in the medical papers, and when the lay papers hear of it they will take up the matter to show the inconsistency of medical opinions and the seeming paradoxes advanced. With the modern tendency of the lay press to exaggerate and magnify and make every item of news as sensational as possible, such discussions not infrequently lead to dangerous conceptions on the part of the lay readers.

In no disease are such seemingly contradictory opinions more dangerous, when copied in the lay press, than in tuberculosis. Thus, for example, there appeared in the Sunday World of January 12, 1908, a lengthy article purporting to be written by Major Charles E. Woodruff, A. M., M. D., U. S. A., with the following headlines: "The Dreadful Things Medical Scientists Are Saying about Sunlight: It Breeds Tuberculosis and Other Diseases, and Consumptives Must Keep in the Shade to be Cured. It is Gradually Eliminating the Blond Type. If You Are a Blond Person You Must Keep away from the Tropics. The Cave Dwellers had the Only Perfect Habitations, and the Modern Theory of Having Large, Sunlighted Rooms is All Wrong."

In the right corner of the page the sun was pictured and across it was placed a danger sign. To the left there were pictured the tubercle bacilli and a handsome woman, a brunette with a calm face, unaffected by the rays of the sun, while underneath there was a picture of a blonde woman staggering and fainting under the rays of the sun to which she

was exposed in the picture.

In the Daily Eagle, of Brooklyn, N. Y., of January 19, 1908, a lengthy editorial entitled Darkness as a Doctrine appeared, beginning thus: "Science makes a high bid for ridicule when some of its distinguished exponents condemn light and sunshine

*Read before the Clinical and Climatological Section at the annual meeting of the National Association for the Study and Prevention of Tuberclulosis in Chicago, June 6, 1968.

as dangerous to human health and life. Even ignorant laymen may laugh when learned physicians tell them that sunlight breeds tuberculosis and other dreaded diseases."

I have since learned how the Sunday World article over the purported signature of Major Woodruff had its origin. It was published without his knowledge and consent, and, according to his own statement, the article "consisted of extracts culled here and there from his book on The Effects of Tropical Light on White Men," but in such a garbled way as to give a false idea, and, of course, the ridiculous headlines were not his. I extend to the major my most heartfelt sympathy, for I know what it means to be misquoted. This present article is, of course, not based on what was said in the World, but on editorials in the medical papers (American Medicine and Medical Record) below referred to, of which the major has acknowledged to me personally the authorship.

Unfortunately the major, no doubt unintentionally, has given, as will be seen from the following extracts in American Medicine, as well as in the Medical Record, to his editorials headings which must attract the lay readers. I refer particularly to the one where he speaks of Dr. Wainwright's advice, which has in large type the words "Dreadful Advice to the Tuberculous," and to the other, "Darkness is Not a Cause of House Tuberculosis" (American Medicine, April, 1907). All important medical papers are read to-day by some of the editorial staff of the leading newspapers. These men are eager for anything which may show what they often please to call the inconsistency of medical science. We should not wonder then that a sensation loving newspaper writer tried to make as much as he could out of such matter as appeared in American Medicine of April and November, 1907, or in the major's book.

Aside from this, there is real danger that the major's statements as to the danger of sunlight in tuberculosis, and that darkness is not a cause of house tuberculosis may be taken up by some of our greedy contractors building tenement houses in New York or other large cities. Let these contractors find a medical authority favoring dark rooms, and the earnest efforts of sanitarians and philanthropists in behalf of tenement house reform may come to naught.

Without my authority I was quoted in the lay press as approving Dr. Woodruff's theories, but, as already intimated, much sad and painful experience with inaccurate newspaper reports has taught me to be resigned to such unfortunate incidents.

But when the matter is taken up seriously in our leading medical and seriously minded lay papers and lengthy editorials are written on the subject, it would seem time that we look into these various statements and seeming paradoxes and see how we may clear the atmosphere of uncertainties.

For lack of space and time I cannot reproduce here all the interesting editorials which have appeared in medical papers on the subject. American Medicine of November, 1907, devotes five pages of editorial comments to this theme. Here are some of the headings: The Danger of Too Much Light in Tuberculosis. Dreadful Advice to the Tuberculous Is that of Dr. J. W. Wainwright, the editor of the *Hygienic and Dietetic Gazette* (October, 1907), "those suffering from tuberculosis should seek the sunshine rather than the shade." The Backwardness of Phthisiotherapy. The Difficulty of Abandoning False Ideas. A Paradox of Sanitation.

The Medical Record of November 2, 1907, came out with a strong editorial under the heading "Contradictory Advice to Consumptives," and very pertinently says, "surely there is greater need of uniformity of advice, for the average layman is unable to sift it out and reject everything except the few essentials on which there are no difference of

opinions.'

Before proceeding further I wish it distinctly understood that I have the highest regard for Major Woodruff personally, and that this paper is not to be interpreted as any attempt to minimize the scientific attainments of this distinguished scholar and gentleman. Most of us are familiar with Major Woodruff's views regarding the danger of sunlight in phthisiotherapy and his views concerning solartherapy in general and in relation to brunets and blonds in particular.

The editorials and articles referred to above, as well as a part of his previous brilliant article, Actinophysiology and Actinotherapy, were in a measure directed against my views on the subject expressed in a paper read before the New York Academy of Medicine² and previous communications on this subject. I am frank to admit that I do not entirely agree with Major Woodruff and that I consider sunlight in general in cool and cold weather and even sun baths at certain times and for certain individuals valuable adjuvants in the treatment of tuberculous patients in our temperate zone.

Concerning the susceptibility of the different types of complexion to tuberculosis I believe to have noticed a few facts, namely that the red haired individuals, that is to say, the Venetian blonds of the French writers, seem more susceptible to the disease and offer a less favorable prognosis. With others I also believe to have observed that many Scandinavian immigrants, who as a rule are blond, when transplanted from healthful agricultural regions in their native country to the congested districts of our large cities offer less resistance to tuberculous disease than the native born American. Among the German Americans, many of whom are also blond. I believe to have noticed more resistance to the tuberculous invasion. On the other hand, among the Irish Americans all of us, I believe,

will have observed relatively little resisting power. Many of the Irish Americans are, however, not blond, but decided brunet. Whether this is due to racial susceptibility or to change of environment, or to both, I cannot state authoritatively.

However, the accompanying table from the United States Census, 1906, shows that the mortality in Norway (198.2 in 1903, 197.4 in 1904) is rather high compared with that of the United States (165.7 in 1903, 177.3 in 1904), and that in Ireland it is the highest of all European countries (223.4 in 1904). Might not this account to a very considerable degree for the great mortality from tuberculosis of the Scandinavian and Irish immigrants coming to this country? Another interesting fact is that Italy, the country which has more sunshine than any other of all European countries, has the smallest mortality from tuberculosis (111.6 in 1903, 117.4 in 1904).

I have visited a goodly number of European sanatoria, and have visited and sent patients to nearly all our States where there exist sanatoria and climatic resorts. I have seen blond and brunet patients do well in all of them, and I have not observed anything which justifies Dr. Woodruff to make, in American Medicine of November, 1907, page 614, the following statement: "It is well known that the results in the sunny South are not so good as in the cloudy North, and here and there they are positively bad, particularly in the case of marked blonds; but the facts are concealed for the commercial exploitation of lands, of perpetual summer, heat, and sunshine.

But one man's opinion, one man's experience, or one man's statistics do not suffice for a scientific and conclusive demonstration. I, therefore, addressed a number of letters of inquiry to men of wide experience in phthisiotherapy, whose opinions I value and whose statements should help us in coming to some satisfactory conclusions on these vital points.

Before giving the tables I desire to express to all the gentlemen who by their prompt reply have been so helpful to me in this difficult task my most heartfelt thanks and appreciation.

I have asked six questions, which read as follows:

1. Do your statistics show that blond patients do better in cold weather or cold climatic regions than those having brown or black hair?

2. Have you noticed the reverse, that is to say,

¹American Medicine, June, 1907. ²Acrotherapy in Cold Weather, New York Medical Journal, May 25, 1997

that brunet patients do better in warm weather or warmer climates than blonds?

3. In your opinion is sunlight harmful in cool or cold weather to the average tuberculous patient, providing he is careful in protecting his head?

4. Do you ascribe the improvement which the majority of tuberculous patients experience in winter in our temperate zones, when "taking the cure," to the cold, to the absence of sunlight, or to other reasons?

5. Have you any experience in solar therapy, that is to say, sun baths, and do you think them injurious or harmful in carefully selected cases under proper supervision?

6. Do you ascribe the relative well being of the tuberculous patients in the morning as the natural sequel of sleep, rest, and quiet of the night, which the average healthy man also experiences, or to the absence of sunlight?

The following is the table:

Summary.

To the first question, which reads: Do your statistics show that blond patients do better in cold weather or cold climatic regions than those having brown or black hair? twenty-two have answered: No; three have answered: Yes; ten have no statistics; eight have no statistics, but think no; one was undetermined.

To question 2, which reads: Have you noticed the reverse, that is to say, that brunet patients do better in warm weather or warmer climates than blonds? thirty-four have answered: No; two have answered: Yes; seven have no statistics; and one was undetermined.

To question 3, which reads: In your opinion is sunlight harmful in cool or cold weather to the average tuberculous patient, providing he is careful in protecting his head? forty-four have answered: No.

To question 4, which reads: Do you ascribe the improvement which the majority of tuberculous patients experience in winter in our temperate zones, when "taking the cure," to the cold, to the absence of sunlight, or to other reasons? twenty have answered: To the cold; eight have answered: To cold and sunshine; five have answered: Not to the absence of sunlight; six have answered: To the cold and not to the absence of sunlight; two have answered: To cold and rest; and two have given no answer to this question.

To question 5, which reads: Have you any experience in solar therapy, that is to say, sun baths, and do you think them injurious or harmful in carefully selected cases under proper supervision? sixteen have answered: Beneficial; seven have answered: Not harmful; twelve have answered: No experience; two have had indifferent results; three have given no answer to this question; one answered he had no experience in general, but in local favorable; one answered that he had no experience, but doubts its efficiency; one answered that he had no experience, but thinks them not injurious.

To question 6, which reads: Do you consider the relative well being of the tuberculous patients in the morning as the natural sequel of sleep, rest, and quiet of the night, which the average healthy man also experiences, or due to the absence of sunlight?

twenty-seven have answered: To rest and sleep; seven have answered: Not to the absence of sunlight; six have answered: Not to the absence of sunlight, but to rest and sleep; one answered he thinks it depends on febrile or afebrile condition of patient; one has formed no opinion; and one has given no answer to this question.

Five gentlemen, Dr. E. R. Baldwin, Dr. Sherman G. Bonney, Dr. Lawrason Brown, Dr. L. Rosenberg, and Dr. Theodore B. Sachs, have expressed the opinion that blonds, and particularly Swedish immigrants, offer less resisting power to tuberculosis than others.

Some very interesting statements were made beside the direct answer to the questions. Many of these seem to me so valuable that I think it my duty to reproduce them here for the benefit of those who desire to study them carefully:

Dr. Edward R. Baldwin, of Saranac Lake, says: Your intentions to give rational reasons why advice should be individualized to tuberculous patients is a praiseworthy thing, and I heartily hope that it will promote sanity in the discussion of the whole subject. So far as complexions are concerned it is a fair statement, I believe, that the typical habitus phthisicus and facies phthisica include a larger proportion of blonds than of brunets and that such patients are usually less resisting to the disease than others, which would account for any differences ascribed by Major Woodruff to the influence of sunlight. Anyway, I have never taken the matter to be of sufficient seriousness to consider in selecting a health resort.

Professor Hermann M. Biggs, of New York, says:

Sunlight is not harmful, but quite to the contrary. Dr. S. G. Bonney, of Denver, Colo., says:

With reference to the color of the hair, one or two thoughts come to my mind. It might be interesting for you to call attention to the fact that among the various races exhibiting a wide divergence in their susceptibility or resistance to consumption, the Swedes, having light hair, display, as a rule, but relatively slight resisting power. On the other hand, the Jews, having almost invariably dark hair and black eyes, exhibit a high degree of resistance to the ravages of the disease. This is particularly noticed in their resistance to the toxemia. The structural changes go on among these races much the same as in others, but the resistance is relatively great, the progress of the disease a rule slow and the process of fibrosis considerably greater than among most other people. At least this has been my experience in Colorado. It is probable that in addition to the radically changed environment and methods

of living among negroes and North American Indians a factor of some moment is the fact that the disease did not flourish to any extent among their ancestors, and therefore its virulence has not become diminished as a result of transmission through various generations, as is true of many of the Caucasian races.

Dr. Lawrason Brown, of the Adirondack Cottage Sanatorium, says:

I have not known that patients with dark hair do better than those with light, but I am under the impression that many Scandinavians, who have light hair, do not resist tuberculosis as well. I do not believe that sunlight is harmful, though I cannot attribute to it any very great therapeutic value, for otherwise patients in the Adirondacks should all do very much worse than they do. Our patients gain most in winter, between August and Christmas, a period when the weather is becoming cooler, and when there is least sunshine. This also happens to follow the normal weight curve; the explanation, of course, I do not

Dr. E. S. Bullock, of Silver City, N. M., says:

I ascribe the better improvement some make in your eastern climate during the cold weather to two factors-stimulating of all functions from cold, and to the greater dryness that occurs during the winter, when moisture is frozen

Surgeon Major C. E. Bushnell, of Fort Bayard, N. M., says:

I believe it to be a general rule that patients of dark complexion stand the sun somewhat better and perhaps do better in warm weather than blond patients. I believe also better in warm weather than blond patients. I believe also that much depends upon the place of the patient's birth with reference to his fondness for sunlight or heat or the reverse, as I have noticed that patients from the southern States do not enjoy cold as do those coming from the north, and this irrespective of complexion. We expect, however, to get better results in practically all classes in the colder half of the year

Dr. P. M. Carrington, of Fort Stanton, N. M., savs:

In connection with this matter in general, I wish to remind you of a statement made by Major Woodruff on page 115 of his book, regarding the excessive light of the Philippines in connection with the prevalence of tuberculosis. You will note that at least in this particular statement he entirely disregards the enervating effects of the excessive heat and moisture, as well as the possible effects of malaria. Furthermore, I am told by those who have visited the Philippines that, at least during the rainy season, there is remployers that, at least during the rainy season, there is employ practically all my night men from among the patients, and I have the general impression that patients doing night duty have improved while on night duty. patients, of course, get their sleep during the day, but they have almost invariably slept in tents, where the light is, of course, intense.

Dr. S. Solis-Cohen, of Philadelphia, says:

I attribute the improvement of tuberculous patients in winter partly to the cold and partly to other reasons, as set forth in my paper on The Therapeutics of Tuberculosis. Hare's System, first edition, Vol. I, and in the article on Tuberculosis in Weber's contribution to my System. Where we can have an abundance of sunlight with the cold, I consider it very much better. I believe that cold, under proper conditions and with sufficiently robust patients, acts as a stimulus to the resisting powers, on the same principle as the physiological and specific stimulus to antitoxine, which the biologists find in toxine.

Dr. William Duffield, of Los Angeles, Cal., says:

The relative well being of the tuberculous person in the morning is the natural sequence of sleep, rest, and quiet of the night, and the nature of the disease. What this cycle is I do not know, but I am confident it is not due to the absence of sunshine, for we often have patients whose maximum of fever and greatest discomfort comes after midnight. Furthermore, in the southwest we find our patients are prone to carry more fever when we have several weeks of rainy or cloudy weather.

Dr. Henry B. Favil, of Chicago, says:

I have only to make a general statement that no observa-tion of mine is sufficiently broad or analytic to be of any value to you in this matter. My opinion would be quite contrary to that expressed by Major Woodruff, but my statistics are not sufficiently organized to have the value which statistics should have.

Dr. J. A. Flexner, of Louisville, Ky., says:

The absence of sunlight, the dull, gray days if long con-The absence of sunlight, the duli, gray days it long continued generally depress our patients here, whether blonds or brunets, and the same applies to the color of the skin, whether it is white or black. I do not think the absence of sunlight has anything to do with this question. As all of us sleep better in the dark the good feelings are fortunately not limited to or modified by our skins or its hair.

Dr. Charles F. Gardiner, of Colorado Springs,

In Colorado we have sunlight and cold, and both are of benefit to the patients. . . Men in "arctic work" during the summer have twenty hours of sunlight and feel much better than during the dark of winter.

Dr. von Hahn, of Dresden, Germany, says:

Not only blond but brunet patients feel better in winter and in cooler health resorts. One can observe that on bright days in winter the patients are not only in better spirits, but the improvement in the lungs is concomitant.

I approve of judicious solar therapy; even the treatment of laryngeal tuberculosis by sunlight with the aid of the mirror has given excellent results.

Dr. Henry J. Hartz, of Detroit, Mich., says:

In a general way sunlight has the effect according to the degree of heat and length of exposure to stimulate the nervous system (vasomotor) or to depress it.

Dr. Guy Hinsdale, of Hot Springs, Va., says:

I consider a cold, clear day, quiet atmosphere with abundant sunlight, the best. You can't kick out one factor and cannot dispense with sunlight—or any one factor. Each element has its place. . . Absence of sunlight can never claim the restoration forever due to sleep. Every one that I know or have heard is in favor of

Dr. G. W. Holden, of Denver, Colo., says:

I would say yes. I have had some experience with sun baths, and have always found them beneficial, if properly regulated, in all cases, whether blonds or brunets. The reaction of sun baths, however, is not as apparent in the brunet as in the blond. The blond burns while the brunet tans. The reaction of sunlight in the blond is more interesting the property of the prope tense, setting up a greater amount of irritation, which I consider beneficial, thus increasing superficial circulation with a corresponding phagocytic increase. In the brunet longer exposure is necessary to obtain the same results. In those patients in whom the expectoration has become tenacious, I usually begin with sun baths, stripping the patient to the waist, and exposing them, front and back, over a period of from three to five minutes, gradually increasing the time of exposure, regulated by careful observation, up to an hour or more. This exposure is followed by proper baths and massage. The sun baths increase the expectoration temporarily, and give a marked feeling of relief.

Professor A. Jacobi, of New York, says:

The blond when young are frequently fat (the juvenile scrofulous), and do mostly better in cold climates. The brunets are often thin and lean and do not do so well in cold climates. . . In clear, cold weather the patients inhale more oxygen and their cutaneous circulation is improved.

Dr. Herbert M. King, of Liberty, N. Y., says:

We have at the Loomis Sanatorium many patients of decided brunet type from the West Indies, Central and South Americas (Spanish-Americans) of mixed Latin races. Comparing these cases, case for case, with the natives of our own belt of similar classification as to their disease, the former respond more quickly and apparently achieve a more permanent arrest than do the latter. I attribute this to the complete radical change of hygienic conditions and climatic environment, and not to their complexion.

Dr. D. R. Lyman, of Wallingford, Conn., says:

The early ambulant patients seem to me to improve as rapidly and gain as much weight here during the summer as during the winter. The "bed" patients do better in the winter for the simple reason that it is easier to keep them warm and comfortable then than it is to keep them cool and comfortable in the summer. By reason of their being confined to bed they cannot take advantage of the shade by breezes at different parts of the ground.

Dr. E. Meissen, of Hohenhonnef, Germany, says:

I have always maintained that as a rule the consumptive will have the best possible chances for recovery in his home climate, and foreign climates should only be selected to suit individual cases. Though sunlight may not have the therapeutic effects ascribed to it by some, this by no means says that it is harmful. General experience probably teaches us that most people feel better on light, bright, and sunny days. Whether this is solely due to sunlight or to the multitude of other factors I am not prepared to say.

Professor J. H. Musser, of Philadelphia, says:

I am not pronounced on the value of solar therapy, although I want all my patients in sun lighted rooms.

Dr. Nicholas Nahm, of Frankfort on the Main, Germany, says:

I ascribe the improvement in the winter to the cold atmosphere on the one hand and to the careful carrying out of the rules and regulations on the other.

Professor William Osler, of Oxford, England, says:

I have had a good deal of correspondence with Wood-ruff about his theory, which I do not accept at all. As I told him, I do not think that tuberculous patients are better under the sunless skies of England than elsewhere, and I do not think we have any statistics to show that tuberculosis is a relatively more fatal disease in Italy than in Norway or Sweden. . . . I have often employed direct sun baths in tuberculosis and neurasthenia and with benefit.

Dr. Edward O. Otis, of Boston, Mass, says:

I do not agree at all with Major Woodruff that sunlight is injurious to consumptives; on the contrary, I believe it is beneficial.

Dr. Jay Perkins, of Providence, R. I., says:

I believe that an alternation of sunlight and cloudy weather has a better effect on the patient's mind (not bodily health) than the monotony of either. . . While I have no statistics on hand upon which to base an opinion, it is my opinion that the majority of my tuberculous patients feel better and eat better towards night than in the morning, unless there is an abnormally high temperature in the afternoon.

Dr. F. M. Pottenger, of Los Angeles, Cal., says:

I have used solar therapy for the past four years, and have exposed my patients to the sun's rays, reflected by a large mirror covered with blue glass, which cuts off the heat rays, and I am convinced that by so doing I have been able to do them a great deal of good. . . I believe that the sun's light is of value, and I am sure that statistics taken from the institutions in the sunny regions will not fall behind in number of cures.

Dr. John H. Pryor, of Buffalo, N. Y., says:

Blonds and brunets will do well in the well known resorts if their conduct and care are supervised by some experts. We must consider the patient, not also the disease, and select the climate and environments after study and experience.

Dr. L. Rosenberg, of the Montefiore Country Sanatorium, Bedford Station, N. Y., says:

The vast majority of our patients are brunets; there are few intermediate types, and a small proportion of decided blonds. My own experience has been that the latter offer very slight resistance to tuberculosis. Question 4 I think I may answer by the statement that whatever advantage of the control of the contro

tage there is in the colder period of the year is not due to the absence of sunlight. (At Bedford we get far more sunlight than they do at the Adirondacks.)

Dr. Theodore B. Sachs, of the Edward Sanatorium, Chicago, Ill., says:

The improvement which the majority of tuberculous patients experience in winter is not all due to the bracing effect of cold air and stimulated metabolism. The effect of cold air on the temperature of febrile patients must also be taken in consideration. Swedes and other blonds of northern Europe, as you know, succumb readily to tuberculous infection in the northern cities of America, but the explanation, of course, lies in the change from country life to the congestion of large cities.

Dr. Sorge, of Alland in Austria, says:

The effects of bright, sunny days are so advantageous that there seems to be no occasion to treat Major Woodruff's views with any serious consideration.

Geh. Hofrat Dr. Turban, of Davos-Platz, says:

We have in Davos every year hundreds of brunet patients from the south of Europe (Italians, Portuguese, etc.). I have the impression that they stand the cold in winter particularly well even if they come from such warm climes as Brazil, etc. We certainly have no better results with the blonds, and I am sure this could be statistically demonstrated in Davos. The brunets do no better in summer than in winter, though, of course, our summers are never very hot. Those who resist the cold least seem the exquisite female blonds with delicate skin. The reason why the results in high climatic resorts are superior to those in lowlands must certainly be ascribed to the great abundance of sunlight in the former.

Dr. Hans Weicker, of Görbersdorf, Germany, says:

My patients do best on warm, windless days; we do not have excessive heat in Görbersdorf. . . . The patients should be considered individually; the pulmonary invalid in the early stages, when he hardly noticed the symptoms, paid relatively little attention to light, shade, warmth, or cold, but in the more advanced stages with increasing anæmia he becomes more sensitive to cold and other meteorological conditions. In the latter stages of the disease he feels best in rooms which the sunlight has warmed. . . . I should like to qualify your question by saying that the brunet southerners belonging mainly to the Latin race

. . . I should like to qualify your question by saying that the brunet southerners belonging mainly to the Latin race are very much more susceptible to cold and feel much more uncomfortable in winter than the blonds from the north. The cause for it I ascribe to their mode of life in the south.

Dr. Wolff, of Reiboldsgrün in Saxony, says:

I firmly believe that in phthisiotherapy there is no relation between the color of the skin or hair and the climate suitable for the patients. The only thing I have observed in this respect is that the reddish blonds have a greater tendency to hemoptysis, and they as all others predisposed to hemoptysis should not be exposed too much to the direct rays of the sun.

I was not able to receive a direct communication from a distinguished phthisiotherapeutist to whom we are indebted for the innovation of outdoor sleeping for consumptives independent of weather and climate. I refer to Dr. Charles S. Millet, of Brockton, Mass. Instead of letting him speak for himself on the subject under consideration, I beg leave to quote from an article of Dr. H. Barton Jacobs in the Maryland Medical Journal of December, 1901: "Dr. Millet also has strong belief in the efficacy of cold water and direct sunshine as tonic agents in the treatment of consumption, and in order to carry out these measures has introduced a well arranged hydrotherapeutic plant, where needle and shower baths and Scottish douches may be applied; also a secluded room on the roof, open to the sky, where the patients take their turn in lying naked in the sun.

From an article by I. W. Kime, Light in the Treatment of Disease, which appeared in the New York Medical Journal* after this address was delivered, I may be permitted to add his concluding paragraph on Therapy of Light in Tuberculosis.

"Liebermeister says: 'Light promotes the general power of assimilation. The more vigorously this goes on the greater will be the vital energy of the body and its power of resistance to everything injurious, especially to pathogenic microorganisms. This, as well as the hyperæmia induced in the limbs exposed to irradiation for a long time, may explain the cures reported by Cicchansky, Poncet, Perdu, and Blanc in cases of local tuberculosis in joints and bones.'

"We use the condensed blue light at Boulder Lodge in pulmonary tuberculosis, lupus, and other chronic skin lesions, and in postoperative surgical tuberculosis. In these affections light, and especially the shorter rays, is an agent of great utility.

"In pulmonary tuberculosis the entire chest of the patient is made bare, and the light, after passing through the blue screen, is thrown directly upon the exposed portions of the body. These rays penetrate the entire thickness of the thorax, having a retarding influence upon the growth of bacteria and engorging the parts with blood. The light is used for twenty minutes each day. Our results since installing the large light have been so much better than before that there is no room for doubt as to the beneficial effect of these rays.

"While by no means a specific, and in the far advanced cases of but little value, in early cases more rapid improvement is noted than was prior to the

use of the light.

"The psychic effect of the light is an adjuvant of no small consequence in cases of pulmonary tuberculosis. If it had no other result whatever we would under no circumstances part with its use."

From these forty odd expressions of opinion from men who have a right to speak authoritatively we learn that the vast majority tell us that the blond does not do any better in cold weather or colder climatic regions than those having brown or black hair; that brunets do not do better in warm weather or warmer climates, that sunlight is not harmful in cold or cool weather, providing the patient is careful to protect his head, and that the improvement in winter is to be ascribed to the cold and not to the absence of sunlight. A similar opinion is held by the majority in regard to Question 6, namely that the relative well being of the patient in the morning is to be ascribed to rest and not to the absence of sunlight. Concerning solar therapy the majority have expressed themselves in favor of it.

Would it thus not seem wise to be just a little more careful in saying the sun is injurious in phthisiotherapy and is not a preventive and curative

means?

I am not going to burden this paper with theories or even facts relating to the effects of sunlight on other diseases. I will confine myself exclusively to its relation to tuberculosis.

Those of us who work among the poor in the tenement houses know only too well how much more frequently tuberculosis develops in the houses

of the poor, where the majority live, sleep, and work in dark rooms where the sun never enters, or enters rarely. Let me quote in regard to this from a letter received as recently as May 2d from Mr. Robert W. de Forest, president of the New York Charity Organization Society and former Tenement House Commissioner:

More than 300,000 persons sleep every night in dark, unventilated interior rooms in tenement houses in this city. These rooms have no windows even to adjoining rooms. This state of affairs is largely responsible for the fact that 10,000 persons die of tuberculosis in New York City each year.

The great and beautiful city of Paris seems to have a like problem before it. From an interesting paper recently read by Monsieur Paul Juillerat and Dr. Alfred Tillassier, dealing with the hygienic conditions found on inspection of certain dwellings in Paris, let me quote the following:

During the year 1906 the inspectors visited 405 new houses, comprising 20,467 suites, consisting of 43,621 rooms, inhabited by 47,130 persons, an average of 1.08 to each room. This density of population the authors do not regard as excessive. It was found, however, that 3,616 sleeping rooms were practically without air and light, sixty-three air shafts being so small as to be absolutely inadequate to the ventilation or lighting of the rooms opening on them. The proportion of dark rooms was found to be enormous, rooms into which the sunlight never penetrated. They were choice places for the lodgment and preservation of Koch's bacillus, and the almost inevitable infection of succeeding tenants.

Scrofulous diseases, local, bone, skin, and joint tuberculosis, we find most frequently among the children of the sunless tenement homes of large cities, rarely among children reared in the country, where they are exposed to a great deal of sunshine. Thus it would seem that the men dealing with tenement house problems and tuberculosis among the masses are in favor of light, and particularly of sunlight, as a powerful preventive factor in tuberculosis. There is no tendency among them to wish to revise the old Persian precept, "where the sun does not enter the physician enters often."

What influence in reality has cloudy weather on the morbidity and mortality from tuberculosis? According to a recent number of the *Therapeutic Record*, twenty years' observation of phthisis over a district at Dartmoor and North Devon in England has convinced investigators that a population exposed to much cloudy weather and strong prevailing rainy winds has a higher death rate from consumption than a population not thus exposed.

Now as to the therapy. In order to understand the therapeutic effects of any remedial agent one must study first its physiological effects, and by so doing we can know the dose and whether excess is harmful. From physiological experiments on men and animals we have learned that too much sunshine is as injurious as its total absence is deleterious. In a very interesting and instructive article on Sunlight and Health' Dr. F. Gillett Byles, of Denver, expresses himself regarding this subject thus:

The physiological effects of sunlight may be said to be increased metabolism, that is, an increased change in the tissue of our body, both constructive and destructive. This is shown by an increased oxydation of the tissues and food,

^{*}Transactions of Congress on Hygiene and Demography, held in Berlin in 1907.

Medical Record, December 14, 1907.

*Journal of Outdoor Life. June, 1906.

New York Medical Journal, July 4, 1908

and an increased elimination of carbonic acid and other waste products. Starving animals lose weight faster in daytime than at night, although all other conditions, such as exercise, heat, etc., remain the same. . . . Sunlight stimulates the action of the skin and causes the better removal of waste matter from our bodies. This action is due to both the heat and actinic rays, the latter producing

perspiration at a temperature lower than the body heat. All of us know that the patient is more cheerful on a bright, sunny day than on a dark and cloudy day. He eats more, he breathes better, and he is more willing to spend the day outdoors. And have not all of us noticed how grateful the sunlight feels to our patients when outdoors taking the cure at a temperature often below freezing? There is something beneficial, psychically and physically, to those patients in the rays of the sun which it is difficult to explain. It has been demonstrated again and again that in our moderate zones the patients in the general hospitals do best in those wards which have the most exposure to the all-beneficent sun. The celebrated health resort, Davos-Platz in Switzerland, to which thousands of consumptives flock every year, owes its reputation mainly to the great amount of sunshine characteristic of that region. And may we not say the same of our equally world famous climates of Colorado, New Mexico, and Southern California, where the number of sunny days each year amounts often to three hundred or more?

From the before mentioned article of Dr. Byles let me quote in relation to this as follows:

The bactericidal influence of sunlight is well known, and is doubtless of great hygienic importance. It is believed that only the actinic rays possess this power; at least the power of sunshine to destroy disease germs is directly proportionate to the amount of actinic rays contained. This is one of the most potent forces in nature in purifying the air that we breathe and the water that we drink.

The atmosphere of an elevated inland region like Colorado has a lower percentage of humidity than is found in the eastern States. This absence of aqueous vapor in the air permits the sun's rays to pass through more directly, and this condition, together with the freedom from clouds and the great abundance of fair weather, causes the bactericidal, hygienic, and curative power of sunlight to be most effective in Colorado.

Thus far for the ordinary influence of sunlight on the average tuberculous patient in our temperate zones under average conditions. That there is another side to this question, and that Major Woodruff is right in some respects, no unbiased observer will deny. There is no doubt that in tropical countries the newly arrived person who has been born and raised in northern climes, be he blond or brunet, unless he leads an exceedingly sober and careful life, and protects himself against the strong actinic rays of the sun and the intense heat of midday, is bound to suffer and become more easily a victim of endemic and epidemic diseases, not excluding tuberculosis. And even in our temperate zones, in hot weather, when every one feels better in the shade, it is of course absurd to expect the patient (unless he feels chilled) to remain in the sun and be comfortable. Every well equipped sanatorium will not only have rest cure galleries exposed to the south, but also such exposed to the north, where the patients can seek the shade and the cool when the sunny side is uncomfortably hot.

In a personal interview I had with Major Woodruff he told me that about one hundred per cent. of the white soldiers who contracted tuberculosis in the Philippines died from this disease. If that is so it would seem best that as many natives as possible are taken in the army for Philippine service.

Solar therapy is not good for every one, even in our temperate zone, but certainly it has proved beneficial in a number of cases in the hands of others and in my own. The directions I am in the habit of giving my patients regarding the sun when outdoors are somewhat as follows: Never walk in the bright sunlight without having your head covered; when taking the rest cure have your body bathed by the rays of the sun, but keep your head in the shade; if the glare of the sun causes your eyes to feel uncomfortable, wear smoked glasses; when you are feverish do not take any sun baths. Should the prolonged exposure to the sun give you headache, cause a rise of temperature, or make you feel uncomfortable in any way, discontinue these sun baths until the physician orders them to be resumed.

I believe in the direct sun baths for tuberculous patients, but I also believe that the utmost caution is necessary. I attach so much importance to this that when ordering sun baths indoors, I give each patient the following specific directions:

The sunniest room should be selected for that purpose. Fixed carpets should not be placed in such a room, and the floor must be kept scrupulously clean.

In a private house, where neighboring windows are often near, the arrangement will be somewhat difficult, and low screens may have to be used. In winter the room should be heated to from 70° to 75° F. By and by, the patient's skin will be less sensitive to the air, and the temperature of the room can be decreased. The room must always be well ventilated. In summer the upper part of the windows can be left open.

The patient undresses entirely, but if he complains of cold feet, he can keep his stockings and even his shoes on, until he has become warm enough and desires to take them off. He places first a warmed sheet around his body, and then a large blanket; he then lies down on the floor in the sun, his head in the shade, and slightly elevated by a cushion. As he begins to feel the warmth of the sun, he uncovers himself gradually until the whole of his body is exposed to the rays of the sun; he exposes his back by turning on his chest. He remains in the sun room for from half an hour to two hours, according to the directions given him by his physician. He may change the recumbent to the sitting position, or walk about.

Like all curative agents in the treatment of phthisis, sun baths should not be taken without the supervision of the physician. Too much exposure may cause irritating skin troubles. To prevent these the patient should cover himself with one or even two layers of the sheet whenever the sun's rays produce a slightly burning sensation. Should these cutaneous complications occur nevertheless, the baths must be omitted for a time and the skin bathed in warm water, and friction with lemon juice applied. Headache or a feeling of discomfort is the signal to stop, no matter how short a time the bath has lasted. When there is a temperature above normal (1980), sun baths should not be taken, and

the patient should remain in bed. Slightly feverish patients may take sun baths, but when experience shows that the baths are followed by an elevation of temperature, they must be discontinued.

While taking the sun bath the patient should do

some deep breathing.

If it is not possible to have enough sun baths while undressed at home, patients should take them outdoors, dressed in light colored clothes—never in black, red, or brown—so as to permit the better penetration of the actinic rays. Patients should always take an umbrella or parasol with them, so that they may shade their heads, no matter where they take their sun baths.

To avoid all possible misunderstanding, I wish again to repeat that the indication for solar therapy and its methods of application will depend not only upon locality (altitude, latitude, or other climatic factors), upon the season of the year, upon the disease for which it is prescribed, but also upon the idiosyncrasies, that is to say, the peculiar susceptibilities, of the individual. Never should solar therapy be resorted to without direction by the attending physician. For patients who, for example, are subject to frequent hæmoptyses, I think direct sun

baths absolutely contraindicated. The number of sunny days in our temperate zone, in addition to altitude, have been heretofore largely our guidance regarding the selection of climate for our consumptive patients. In my Maxims for the Selection of Climate in Tuberculosis' I say, in relation to this the following: The ideal climate for the average tuberculous patient in the earlier and more hopeful stages of the disease is the one where the extremes of temperature are not great, with the purest atmosphere, relatively little humidity, much sunshine, and all conditions which permit the patient to live comfortably out of doors the largest number of days of the year, and the largest number of hours out of the twenty-four. For tuberculosis of the bones and joints and scrofulous affections of childhood the seacoast climate in our temperate zones comes nearer to deserving the term specific than anything else. The peculiarly beneficial influence of seacoast climate in bone and joint tuberculosis is doubtlessly to be ascribed to the aseptic and ozonic quality of the air, and the iodide and other salts suspended therein. The native locality of the tuberculous must be taken into consideration when making a climatic change. The patient who spent his early youth in Norway or other parts of northrn Europe, or one born in Massachusetts, Maine, or northern New York, where the winters are rigorous, will usually do better in such climates as Colorado, the Adirondacks, Sullivan or Orange counties of New York offer. The sons and daughters of sunny Italy and our American born citizens from the warmer zones will do better in climates such as are to be found in southern California, New Mexico, Arizona, North and South Carolina, Virginia, Florida, Bermuda, etc.

To the foregoing rule there are exceptions, and besides considerations relating to nativity one should be guided in a large measure by the patient's personal experience. For example, a cold climate may be selected if the patient has found by experience that he feels more comfortable and less dis-

tressed in winter. A change to a warmer climate is indicated when the reverse is the case. When the experience of the patient has demonstrated that he effet better when near the sea soast, or vice versa, this factor must also serve as an indication for his domicile when seeking cure.

There exist idiosyncrasies in regard to climatotherapeutics and aerotherapeutics as there exist in hydrotherapeutics, electrotherapeutics, and medicinal therapeutics. These idiosyncrasies cannot be discovered beforehand, they can only be learned by

experience.

I am free to confess that I have never been guided by the color of the patient's hair, nor his complexion. There are very few pronounced blonds in this country; one occasionally sees blonds among the Italians and people from other parts of southern Europe, and brunets among people from northern countries. The vast majority of our patients are neither decided blonds nor decided brunets, of course, leaving aside the negro race.

I distinctly remember, however, a few patients who did not like cold, and they were decided blonds, and I also remember some black haired patients who always longed for the winter because they thought they felt much better during that period.

In the editorial in *American Medicine* of June, 1907, already referred to, we read the following:

The difficulty of abandoning false ideas is very nicely illustrated by a remark of Dr. Thomas Darlington, of New York, in an address to the American Climatological Association. He mentioned the good results of the outdoor treatment in the sanatorium at North Brother Island, where the climatic conditions are "distinctly unfavorable," advanced and apparently hopeless cases being cured. Then he said that this took place "despite climate." It seems more logical to reverse the matter and call the conditions distinctly favorable if they are curative. What was once considered bad climatic conditions are now known to be the best, but it will take a long time for the profession to reverse its ideas.

It is my privilege to be the senior attending physician of the institution referred to by my distinguished friend, Dr. Thomas Darlington. Thus I believe I can speak somewhat authoritatively on this subject. If there is any sun in New York my patients of North Brother Island make the very best use of it. They always feel better when the sun shines, and if the day is pleasant in New York City it is many times more pleasant on our beautiful island. It is due to Dr. Darlington's and Dr. Biggs's indefatigable energy that we have now, in Otisville, at a considerable elevation, and where the climatic conditions are still better than on North Brother Island, a sanatorium for the consumptive poor where we send our patients who, upon examination, present the best chances for recovery, because we think in this mountain sanatorium there will be still more pure and dry air, a still more invigorating atmosphere, and still more sunlight.

I firmly believe that we can refute with our present knowledge the accusations which have been brought against modern phthisiotherapy by the lay and even by the medical press, that we are inconsistent, incongruitous, and paradoxical in regard to our views on the value of climate, sunlight, cold,

and warmth.

The great success in modern phthisiotherapy is not in generalizing, but in individualizing our remedial agents. We allow a tuberculous patient who has a good, vigorous reaction to take cold douches, while we warn the one with a feeble circulation, pale and easily chilled, against doing so, and tell him to content himself with tepid ablutions. For the patient with much underweight, but whose stomach has been put in good condition, we try overfeeding, or, as the French call it, suralimentation. In another patient we content ourselves with giving him only three good meals, and simply try to maintain his weight, because in this individual case experience may have told us that stuffing the patient was inadvisable. Overfeeding in such a case might produce discomfort, dyspnœa, and altogether too frequent digestive disturbances. In the patient with no active lesions and whose expansive power is very poor, we may insist on breathing exercises; in another with active lesions, or with a tendency to hæmoptysis, we may caution quiet breathing.

When a patient is in the early stages of the disease we try to train him to sleep outdoors in cold, in wind, and weather; when the patient is hopelessly ill we know it is cruel to thus expose him to cold and discomfort. We consider alcoholism a predisposing factor in tuberculosis, yet there are instances, particularly in the latter stages of the disease, where we occasionally prescribe an alcoholic stimulant and find it beneficent. Because we vary our treatment to the patient's individual conditions, sometimes even to his likes and dislikes, but always with the one point in view, to do the best for him, what seem like paradoxes in modern phthisiotherapy to the uninitiated and the superficial observer, whether they refer to sunlight, air or water, climate, medicine, or other remedial agents, are in reality prompted by the highest considerations and the most careful and painstaking individualization.

None of us believes that modern phthisiotherapy

is an exact science.

We all know that there is much to be learned yet before we can say we have mastered the disease. If Major Woodruff's past and future contributions on this subject shall aid us to a still better understanding of phthisiotherapeutics or prevention of tuberculosis, I am sure all of us will be most grateful to him.

We may err, but we surely will make fewer mistakes if we try to benefit by the experience of the majority. In regard to the influence of sunlight in tuberculosis and the value of solar therapy, let us say with St. Paul: "Prove all things; hold fast that which is good."

16 WEST NINLTY-FIFTH STREET.

* U DANGERS OF EXCESSIVE SUNLIGHT IN TUBERCULOSIS.

BY MAJOR CHARLES E. WOODRUFF, Fort Wadsworth, N. Y., Medical Corps United States Army.

I thank the editor of the New York Medical Journal for the privilege of replying to Dr. Knopf's paper in the same number in which it appears, for unless it is immediately answered it will do harm. Continued investigations of the effects of light have revealed no evidence which will change the conclusions published three years ago, as to people in

health, that, while excessive sunlight is always harmful Ito them, that fact is not proof of the need of darkness, and that "we do need the stimulation of a little light." How much, if any, of this stimulus is needed by the sick is another matter, and the recent evidence is causing much doubt as to the correctness of old opinions, particularly as to tuberculosis. The editorial in the *Medical Record* which Dr. Knopf approves was written for the sole purpose of warning against the publication of views not warranted by the recently discovered facts. It is doubly regrettable to find it stated that anyone advocates dark living rooms for any purpose.

The article on Actinophysiology and Actinotherapy in the American Medicine, April (not June), 1907, was not directed against his views published in the New York Medical Journal, May 25, 1907-a month later-but reference was made to his article of January 19, 1907, in the Journal of the American Medical Association, in which he advocates light colored clothing so as to transmit light. If thick enough for winter wear it is just as opaque as the dark. Nor were certain editorials in the American Medicine directed against his views on the subject (presumably light), but to praise his article calling attention to the benefits of cold air, and combat his explana-tion that cold was "vitalizing," whereas every one knows that it is as devitalizing as anything can be. No explanation of the effects of cold air has ever been published.

I never told Dr. Knopf "that about one hundred per cent, of the white soldiers who contract tubercuplosis in the Philippines die from this disease," but that all cases in white people in the tropics promptly perish unless they are sent home. The facts were discovered by the army as early as 1900, and it was necessary to issue a military order that the cases should be hurried to the transports as soon as found. Some would die while waiting a boat, and even now, with all our haste, they not infrequently die before reaching San Francisco, but if they are sent home at once, before any headway is made, recovery fol-

lows in the usual percentage of cases. It was this frightful rapidity and fatality of the disease among soldiers in the tropics that led me, as a military sanitarian, to try to find out the causes. There must be many reasons for this loss of resistance. The heat is undoubtedly the main one, because cases here make the most improvement in winter. Some deteriorate in our northern summers, which are far from tropical. Humidity always increases the effect of heat, as it interferes with evaporation of perspiration and the normal loss of body heat in this way-perhaps one of the reasons why arid climates are beneficial, particularly if they are also cold. I had already proved that excessive light was harmful to those with unpigmented skins, and that their death rate was higher in the Philippines than the brunets. Sir Alfred Keogh, medical director of the British army, writes me: "We hope to take up the question of the effect of light on the health of troops before long. A considerable number of experiments were made in India at the time your book first came out, which entirely supported your theories as to the depressing effects of direct exposure to the sun being due to the actinic rays, not to the heat rays

It was presumed then that possibly excessive light was another cause of the tropical tuberculosis susceptibility, and an investigation was started, which has brought forward many facts at variance with accepted theories as to the benefits of unstinted sunshine in prevention and cure. It was also found that in the mass of tuberculosis literature there was not a single bit of proof anywhere that sunlight in any dosage was an essential in prevention or cure, but that the evidence pointed the other way. For instance, every recorded experiment with excessive light showed that it was lethal, and that in less amounts it injured living tissue, there being, of course, great variation in resistance. All short rays are used in therapy to destroy something. amazing of all, it was found that in Finsen's cure even the concentrated light is not strong enough to kill the bacilli, but does injure the atypic cells, and that it also acts like other irritants used in curing lupus, but no one knows why or how. (Mally, Revue de chirurgie, August 10, 1907.) Our former opinion that light penetrated our bodies sufficiently to kill the bacilli must be abandoned.

It was found that in every part of the world, hot or cold, man was pigmented in direct proportion to the maximum intensity of light. In cloudy Scandinavia he is blond, but his neighbor, the Laplander, like the Eskimo, is pigmented against the awful snow glare. Koehler-Hillier's map (see J. B. Huber's Consumption and Civilization) shows that the tuberculosis mortality rate per 1,000,000 living is least in the cloudiest parts of Europe. The least city rates are also in Amsterdam and London, both cloudy, the latter having only 1,027 hours of sunshine, while the highest are in sunnier places like Moscow, St. Petersburg, and Vienna. Walsh, of Phipps Institute, is reported as saying that patients do unusually well in Pittsburgh and London. the mountains of Switzerland, Austria, and Germany it is cloudy nearly half the time, and yet the results are excellent. In our own Adirondacks there is even a greater number of cloudy The census table of tuberculosis mortality of various countries must be interpreted as to racial immunities, state of nutrition, and methods of living, as well as heat and light; but it is noted that the three worst countries —Austria, Servia, and Chili-are far from cloudy, but the three best, omitting Italy, are Netherlands, England and Wales, and Belgium. Italy has many cloudy mountainous climates, which reduce its mortality for the sunny coast cities have very high rates.

Hoffman's statistics (p. 119, Huber) show that the most fatal trade is stone cutting, 43.1 per cent. of deaths being from tuberculosis, yet stone cutters who work in the dark—miners—have only 6.4 per cent. In the 1908 report of the medical examiner in chief of the Royal Arcanum, Dr. Sanford Hanscom, East Somerville, Mass., granite cutters head the list of occupations as to tuberculosis mortality and miners end it. This latest table is so important that it is quoted in full to show that light or darkness might have opposite effects from what we now believe. It is also to be noted that in the other occupations it seems to be a question of fresh air more often than light or darkness, yet it is remarkable that those having the most light suffer most and those having the

least have the best record, and some indoor workers have low rates and outdoor workers high ones:

If excessive sun exposure does good the blonds should do best, for more light penetrates their skins, but if it does harm they should suffer a higher mortality. As a matter of fact, Bartholomew's Physical Atlas of Meteorology shows that marked blonds flourish only where it is cool or cold and there is less than 1,250 hours of sunshine per year, and that as the hours of sunshine in Europe increase the more brunet is the population. Migration into a sunny land is followed by extinction sooner or later. Bouchereau (Anthropologie, Paris, 1900), in a study of the central plateau of France, shows that even there these migrated blonds are losing ground, being more subject than brunets to certain fatal diseases, tuberculosis especially. The inhabitants of the northern, cloudier parts of France have always been more strongly blond, and Louis XIV sent ship loads of these blond women to populate Canada, yet they have lost ground in that sunnier place, for the population is now strongly brunet. The type dies out here, too, for in spite of enormous blond immigration the marked blonds are very few, and they are mostly immigrants, or their immediate ancestors were. The blond Puritan immigrants of New England have left scarcely a trace, and the French blonds of New Orleans are all gone. Something kills them off, My own statistics showed that the blonds had a higher death rate in the Philippines, and the surgeon general's reports show that the soldiers in this country are healthiest in the darkest spots.

Though blond Scandinavians have less resistance in America it must be remembered that in their native cloudy home, which has one of the least rates in Europe, they are very resistant and curable. They cannot stand city life nor light countries, and city life is more glary than the country. Negroes, on the other hand, were nearly immune in slavery days, though enveloped in darkness by their skins, but now they show great susceptibility, due partly, if not entirely, to unsanitary living, yet under proper treatment, it is now reported from Fort Bayard, the prognosis "does not seem to be so absolutely bad as it is considered to be by many in the north" (Bushnell), and these men are treated in darkness even if given sun baths. Unfortunately negroes are generally advanced cases when first seen. Significantly enough, both army and navy experience shows that negroes do not stand a very high heat (over 110° F.) as well as white men-the reason being probably the absorptive power of dark surfaces. It is to be noted that heatstroke among whites is not very common either in the moist Philippines or in the greater summer heat of our arid West, but in both places light prostration is more common. Many British military surgeons now believe that sunstroke in India is due to the actinic rays, though they do not define "sunstroke" (Journal of the Royal Army Medical Corps, July, 1908. See also Medical Record of August 8, 1908).

Space does not permit even reference to all the discrepancies discovered, but in every case they could be explained on only one hypothesis—that excessive light was harmful. If this could be proved true, then we would have something to go on, in preventing the soldier mortality in the tropics. Only two specialists had noted the matter, Burton-Fanning, who found that even the sunlight of England caused anorexia, fever, headache, and prostration, and White, of Colorado Springs, who found that our intense western light caused fever, and both advised shade, and Huddlestone (Medical Record, February 9, 1907) stated that two children convalescent from pneumonia, who had been given outdoor exposure, actually suffered from "sunstroke" as a consequence.

In discussing the matter with Dr. Livingstone Farrand, secretary of the National Association for the Study and Prevention of Tuberculosis, he suggested a questionaire, and I prepared the following one, which he most kindly distributed where he knew statistics were kept:

The modern treatment of tuberculosis has now been sufficiently tried to yield enough facts for a distinction of cases to determine the influence of climate in each ethnic type. It is an elementary biological law that every species of living thing is physically adjusted to its climate, and perishes in a markedly different one—a law applicable to each type of man. The proofs are conclusive, for instance, that skin pigments have been evolved to protect against the actinic effect of the sun's rays, for in every climate, hot or cold, the degree of pigmentation varies with the intensity of light, which, like rays from radium and Crookes's tubes, is invariably injurious to living protoplasm if applied in sufficient intensity. The facts are set forth in my work on The Effects of Tropical Light on White Men, and have already called forth sufficient data to revive the old suspicion that blonds, though vigorous in Scandinavia, are more or less injured by the sunny American climates, and produce more cases of tuberculosis proportionately than brunets—a difficult matter to prove, as we have no data as to the relative numbers of the two types in our population. There is more evidence that in very sunny climates and in summer time and in institutions where sun expo-sure is a feature, the very blond do not improve as rap-idly as the dark brunet, and that there is a smaller percentage of recoveries in all cases in sunny climates than

in cloudy, and a more rapid decline of incurables—statements of such importance that they should be proved or disproved at once. As such an investigation may show that climate is a great therapeutic factor after all, and also that what is beneficial for one type may be harmful to another, it is hoped to collect as many data as possible.

that climate is a great therapeutic factor after all, and also that what is beneficial for one type may be harmful to another, it is hoped to collect as many data as possible. What is needed is a classification of all cases into three groups: (1) Marked blonds, like the Baltic type; (2) marked brunets, like the Mediterranean; and (3) those of medium complexion who constitute the majority of patients, but who will not furnish as valuable information for comparison as the first two.

Anything you can do to forward this investigation by furnishing statistics as per enclosed form, or any other

facts known to you, will be much appreciated.

The responses were prompt and generous, though generally to the effect that no attention had ever been given to the subject, but that statistics would be kept in the future. Nevertheless some most valuable data have been sent. It was evident that such an investigation would take a year or longer, but Dr. William Osler, though disagreeing with me, requested me to prepare a preliminary report for the September Congress. I proposed doing this, but Dr. Vincent Y. Bowditch, of Boston, kindly warned me that, as it would be too late to get on the programme, the paper would only be read by title, "even if it passed the censorship." I take this opportunity, then, of presenting the facts so far gathered.

It is quite evident from Dr. Knopf's paper-he being a director of the association which organized the Congress,—that the matter of the damage of light will not be given any more courtesy, than was given to Dr. George Bodington's opinion in 1840 that the disease should be treated in the open air (see Huber's Consumption and Civilization). In 1840 the profession was strongly of the opinion that cold air was fatal, and they drove Bodington's patients away and closed this first modern sanatorium. Dr. Knopf is repeating the error-instead of giving facts, he is giving opinions of the leaders. His authorities have never noticed any harm from excessive sunlight, not because it does not exist but because they have never looked for it. Bodington's opponents never noticed the harm done by indoor treatment and their opinion likewise did not prove that there was no damage by it. Bodington saw that the evidence all pointed the other way, and likewise there are a few now, who have observed facts which point the opposite way than the profession as a body thinks. For instance, Bacon, of Tombstone, Arizona, says: "My personal notion is that the light races oppose the least resistance to tuberculosis of any of the types." Nahigan, of Seton Hospital, Spuyten Duyvil, New York, says: "I, however, think that marked blonds succumb to the disease more readily than brunets." Petit, of Ottawa Tent Colony, Illinois, says: "Scandinavians as a rule are not very satisfactory patients from the standpoint of results." Dr. H. Edwin Lewis, of New York, noticed in his sanatorium in Burlington. Vermont, that he did not get good results from sun exposure, and the following years he kept patients in the shade with more improvement. Bullock, of Silver City, New Mexico, quoted by Knopf as to cold, writes: "I am very careful even in winter, about exposing my patients to direct sunlight as I learned, a posteriori, long ago that direct sunlight was bad for them. It agrees with very few to stav in direct sunlight even in fairly cold weather,this independent of coloring or, as you say, ethnic

type. As a therapeutic means I gave up direct exposure long ago." By Bartholomew's map, New Mexico has as much light as North Central Africa, and the natives of each place are heavily pigmented, so that our brunets, even of the type of southern Italy, are insufficiently protected against New Mexico's sun, and the lighter brunets from central Europe of course are more injured and blonds the most. Dr. John Carling, of New York, noticed at the Park Ridge Sanatorium that "brunets respond much better to open air treatment than do blonds." A prominent physician of Philadelphia, where the sunshine is not as severe as in Silver City, says: "I am in accord with the modern view that sunshine is less important in the treatment of pulmonary tuberculosis than was formerly supposed, although I cannot go quite so far as to assert that an excess of sunshine proves injurious, simply because this observation has not fallen within my personal observation and experience." Rosenberg (Montefiore Home, N. Y.) says that Jews who are decided blonds "offer a very poor prognosis; they are apt to be hæmorrhagic types or those in which the disease is rapidly progressive." But Flick (Phipps Institute, Philadelphia) says: "So far as I have been able to make out from our statistics, they do not support the view that blonds are more subject to tuberculosis or recover from it less readily than brunets. Our statistics are not of a large enough number of cases to warrant conclusions, however." Courtois-Suffit and Tremolières (La Pratique thérapeutique) have also advised that sun exposure be avoided and that patients carry umbrellas.

Summer experience with field hospitals shows that all fevers rise in hot, glary tents, and are reduced by removal to cool, shady houses. Joseph Walsh sends me the following from the Phipps

Institute:

This seems to indicate that blonds do furnish more than their share of Philadelphia's population and surely do not improve so well as the brunets.

The following table is the summary of cases reported by Nahigan (Spuyten Duyvil, New York), Lyman (Wallingford, Connecticut), Montgomery (Philadelphia, Pennsylvania), Joseph O'Malley (Philadelphia, Pennsylvania), Pottenger (Monrovia, California), Barlow (Los Angeles, California), Bacon (Tombstone, Arizona), Holden (Denver, Colorado), and Carrington (Fort Stanton, Mexico), to whom my thanks are given. A few others reported also, but as they divided the cases merely into blonds and brunets the figures are not included.

| Total | 30 18 | 101 132 2 85 1

Fairly safe generalizations can be based on 1,567 cases, though such varied standards were taken for blonds and brunets as to mar it somewhat. In addition, there is an amazing difference of opinion as to what constitutes cure or arrest, one private sanatorium reporting "apparent cures" of ninety-three per cent. of incipients, fifty-five per cent. of moderately advanced, and fourteen per cent. of advanced cases; "arrest or improvement" in nearly all others, no improvement in less than three per cent., and none progressed. Another reports no cures and few arrests.

Such as they are, the figures show that marked blonds furnish more than their share in all parts of the country and are less curable than marked brunets, and more die in equal times. The facts are the same as recorded in the Twelfth Census (Volume III) that different races in this country have tuberculosis rates approximately proportional to their blondness. The Irish head the list, and Dr. Alexander Lambert writes: "I have the distinct impres-

sion that the Irish with the light brown hair, blue eyes, reddish mustache and beard, is a much more frequent type in the tuberculosis wards than the darker type." Northern Ireland is as cloudy as Scandinavia. Ripley says that northern France is more Teutonic (blond) than southern Germany, and the same may be said of Ireland as a whole. difference between blond and brunet death rates in the United States is sufficient to change the type of population in two centuries from this disease alone, not mentioning other complaints more common in marked blonds. Northern Germany and France being cloudier than any part of the United States except our eastern mountains and northwest coast, should show no such difference in the two types, and neither should Scandinavia or northern Scotland, which are the darkest places in Europe. But differences have been found in southern England, where the blond population is not maintaining itself.

Owing to different methods of treatment in sunny climates and the little reported from the cloudiest places, nothing can be determined now as to the relative curability of blonds in the two places. Only the deaths are sure. According to these reports, if one hundred blond patients of all stages are kept in the northeast, sixteen per cent. die within a year or two, but if they are sent to the southwest, twentyfive per cent. die. Sunny Florida was abandoned because of its awful results. The mortality among the white population of Virginia is a disgrace to civilization, and a Richmond doctor calls the matter of light a "sophistry," that is, if the editor of the News Leader is correct. Even the brunets have a large death rate in the southwest (19.5) as compared with the northeast (13.5), as the light difference is the same as between Austria and Sahara. The average heat is not much different between the northeast and southwest places, so that factor can be eliminated.

The most remarkable statistics are presented by Dr. John E. Bacon, of Tombstone, Arizona, of patients of whom he had personal knowledge in three years. It seems to show that in blonds not under sanatorium management the terrific light of the place is very fatal, yet one man has stated that it is not "of sufficient importance to consider in selecting a climate"

Miss Clara D. Motthews, teacher of methods, City Fraining School, Elizabeth, N. J., in writing of the

advice as to treatment of nervous children in the lightest months, says:

I have followed the suggestions made with very notice-the results in several classrooms. On very bright days I carefully shaded the windows before the children came in from the playground. The relief to the children was immediately evident, and they worked quietly the whole afternoon. As a further test, I left the windows open the next bright day. The children were restless during the entire session. Only a short time ago, while visiting classes taught by pupil teachers, I approached a room from which evidence of great disorder could be plainly heard. I entered the room quietly, drew the shades, and noted that the children were quiet in a very few minutes. The same children were in the best order when I returned to the room later in the afternoon. I have been so much impressed with the results of carefully regulating the light, that I now instruct all girls in my method classes to try this plan of securing quiet work during the trying spring days.

If such marked stimulation follows undue exposure of healthy children, surely we must expect greater harm in the case of more susceptible consumptives. It is not surprising, then, that the only observations reported from Manila to date state that of the five white soldiers recently observed with tuberculosis, four were marked blonds and one a medium type.

As the only difference between a blond and a brunet is the greater penetrability to light of the former, it must be a brave man indeed who will prescribe unstinted light—almost as brave as the physicians of 1840 who kept their patients indoors

and saw one hundred per cent. die. Carrington says that he has been informed that in the Philippines "at least during the rainy season, there is very little sunshine" which shows what false

climatic conceptions obtain.

The stimulating effect of sunshine is so well known that it is a waste of time to mention it again, but why we should want the patients stimulated even to the point of exhaustion is a mystery. Sleep and rest are said by all to be the reason why cases are better in the mornings, yet sunlight prevents both sleep and rest. It is so illogical then to give it.

Knopf's questions I and 2 show misunderstanding of the matter, for it is a question of light as well as heat. Cold climates differ, and blonds should do better in some than in others. Such brunets as Esquimaux perish in warm places, they are only protected from the light of snow glare in summer when their heads are exposed. Questions 3 and 5 are amazing, for what good or harm can a sunbath do, if the patient is enveloped in opaque clothing and his head protected? Yet hundreds of physicians are giving such "sunbaths" and asserting good results from them. It is as futile as giving medicine in insoluble capsules, so that it passes through the intestine unabsorbed. Questions 4 and 6 properly bring out the benefits of cold air and rest but give no evidence on the matter of light.

The most amazing thing about the paper is the frequency with which my opinions are mentioned by physicians, when I have not yet come to any conclusion whatever, except the one which Dr. Knopf approves, that excessive light is harmful. The points upon which I am in complete ignorance are exactly what constitutes excess, and whether a less dosage does any good. Sorge, in Austria, says: "The effects of bright sunny days are so advan-

tageous that there seems to be no occasion to treat Major Woodruff's views with any serious consideration." I wish I knew what those views are. But as Austria has only 1,700 hours of sunshine and our southwest over 3,000 and that very intense, it is quite evident that a "bright sunny day" in Sorge's mind would be considered very dull in New Mexico, or the Sahara.

Turban mentions the abundance of sunshine in high altitudes as the reason for better results, whereas mountainous resorts are notoriously less sunny

than the lowlands.

Knopf refers to the long known fact that in crowded windowless rooms the disease is horribly prevalent, but what right has he to assume that it is due to the darkness and not to the heat and bad air, when miners in the well ventilated mines are so free of the disease? No control experiments have been made in which the tuberculous and healthy were subjected to identical conditions, except one group shaded and the other exposed to sunshine such as in Arizona. To be sure, Trudeau's experiments with tuberculous lower animals show that those treated outdoors did far better than those kept in a dark cellar, but was the poor light of the Adirondacks the factor or its cold air? The vast majority of animals live in the dark, even plant cells are protected under the bark or green pigment of leaves. Nor can it be understood why Byles and Knopf desire the increased oxydation of tissues and food by light, when it is so necessary in this disease to reduce expenditures. Byles has stated (Medical News, November 26, 1904) that the exhilaration of Colorado is so marked that residents must sometimes be sent away permanently for insomnia, and he says that nervous people should not go there. The latest thing investigated about consumptives is their almost universal neurasthenia,-some so bad even after recovery as to be considered insaneand therefore these are the very invalids not to be sent to exhilarating places.

The statement that patients in the sunniest wards do best is not always true, if ever. Ransom, at the Dannemora prison, found that they did best in the shadiest part of the ward, and northern New York is not very sunny either. Patients are carefully shaded in the fresh air cure in the suburbs of Berlin under Lennhoff, Becher, and Pannwitz. Certain places owe their "reputation to the great amount of sunshine," but Lourdes has a "reputation" too! The climate of Milan fulfils Knopf's ideal and London does not, yet it would be dreadful to send a patient from London, where the 1904 tuberculosis death rate was 166 per 100,000, to Milan, where it was 254, and London is notorious for its overcrowding, fifth, poverty, and underfeeding—all causes of increased

mortality from tuberculosis.

Even in cloudy England, Sherwood Forest Sanatorium (Huber, p. 282) has its verandas so built as to shelter "from the wind in winter and the sun in summer." Other English institutions face the rooms to the south to get the light, and then find that they must shut it out with "outside blinds and light inside curtains." In France, the sanatorium at Caingnon is actually closed in the hot months.

One of the most absurd articles ever written is that by Dr. T. B. MacDonald (Journal of Tropical Medicine, May 1, 1908) who lives in Australia in a climate resembling Alabama, and because he finds that the farmer's children are as healthy as Alabama babies, he concludes there is nothing in pigmentation after all, and that Nature is wrong to go to so much trouble in light countries as to pigment the natives

Osler said that perhaps one reason for good results in rainless districts is the fact that patients spend more time in the open, but it is reported to me that results are excellent on our northwest coast where it rains most of the time. Dr. Knopf says the sea coast is so good as to deserve the term speci-fic, but Carlin, of New York, reports better results inland than on the coast. What must we say of the alleged benefit of ozone, iodides, and other salts in the sea air? Are they present in sufficient amounts to have physiological effects? Who has proved that they do good if they are present? There is nothing recorded on the subject. Knopf's statement that people born in warm zones do better in such climates is not correct. It depends on the type of man, sick Englishmen born in India are sent north to get well.

We knew beforehand that the vast majority of physicians advocate sunshine even in excess, but that does not prove anything, any more than in Bodington's time. Dr. Knopf well quotes "prove all things; hold fast that which is good," but his paper presents no proofs whatever that light is good enough to hold fast, and the modern idea is that it is not so important as once thought. He objects to the charge that phthisiotheraphy is backward, yet that charge is true and due to faulty observations. It is a dreadful condition when a curable disease carries off seventeen per cent. of all patients within a year or eighteen months even under sanatorium treatment, and twenty per cent. more progress or are unimproved. It is amazing that so many phthisiotherapeutists express such positive opinions on a subject of which they confess they have no data to base any opinion. No wonder eight per cent.

of our people die of consumption.

Experience with hospital gangrene in the civil war showed that patients would recover in tents who would have perished in the overcrowded septic hospitals, but that was mostly in the winter. now find, in field hospitals in summer, that hot, glary tents increase the fever of all diseases, and that removal to a cool, shady room causes a marked decline of temperature. Typhoid fever patients in Cuba, for instance, treated in a modern hospital near Havana two years ago, had no mortality, but of those in the interior in improvised hospitals, nearly seventeen per cent. died. We are teaching that the proper thing to do with the sick in summer is to remove them from tents. Such exposure of the tuberculous to heat and light in tent colonies may account for part of the bad results in summer. Experiments with a tent I devised, with a dark canvas roof, showed it to be markedly more comfortable than the ordinary ones, and it might be beneficial for consumptives.

All of us, sick or well, must use opaque clothes

in our summers in the south and perhaps also in the north. Sambon, of the London School of Tropical Medicine, has invented an opaque cloth for the tropics, having a light outer surface to reflect the heat. As a matter of fact dark outer clothes are cooler than white if we are in the shade or in evenings, as they radiate heat better, but of course light colored outer clothing is necessary in tropical sunshine, and then dark undergarments are needed. Any opaque color will do. Our soldiers preferred the dark blue shirt, but the United States Quartermaster's Department is making some experimental tropical underclothes and hat linings of orange red, though I do not know the scientific reasons for the selection of these gaudy colors. Umbrellas and "merry widow" hats are not unmixed evils in summer after all. The army abolished its most important tropical headgear—the helmet—because the soldiers could not sleep in it in campaigns.

The isonephs (lines of equal cloudiness) and isohels (lines of equal duration of sunshine) do not give proper data for comparing climates. What we need is a map showing the maximum intensity of summer light in each place in the world, and also the total annual amount of light recorded by one of the numerous photometers. Then in selecting climates we could use the isophots instead of the isotherms, and instead of isotheres (lines of equal places of maximum intensity of summer light-and summer heat) we would use the lines connecting there is no name vet coined for such lines. The weather bureau could do it for this country but have not-indeed some of the weather observers will not learn anything in this line of their profession. One of them kindly and genially writes me that I am a "moss back" and says "I have not read your book, nor is there any probability of my doing so, as it seems to me that the book and your letter must be the products of a disordered imagination"—"I do not propose to assist in exploiting any man whose 'ego' and 'major' are so pronounced." "But it is apparent that you are the most ordinary kind of notoriety seeker." So the hundreds of thousands of consumptives cannot count on him for any assistance.

As Dr. Knopf has furnished no facts, I take this opportunity of begging data from everyone in a position to give them, carefully separating the cases into marked blonds, marked brunets, and medium types, and giving the ultimate results separately of incipients, moderately advanced, and advanced cases, the time under treatment, and whether sun baths are given to the naked body. There should be a uniformity in reporting results and for the purpose of this inquiry it is sufficient to divide them into (1) cured and arrested, (2) improved, (3) unimproved and progressed, (4) died. When enough data are collected to make safe deductions in details, a full report will be presented, and then we all can afford to have opinions, and Dr. Knopi can inform his medical friends in his dark native land what our opinions really are. Then also the British Medical Journal may not say it is all "little short of ridiculous," and the next International Congress will not exhibit so many devices for the exposure of patients to the sun to kill nine per cent. of the blonds.

CANCER OF THE RECTUM.

A Study of One Hundred Consecutive Operations for Malignant Growth of the Rectum and Sigmoid.

By JAMES P. TUTTLE, M. D., New York.

(Continued from page 440.)

ABBREVIATED HISTORIES.

Case I.—March 20, 1891. Mrs. M. A., age sixty. Thin, anæmic, wasted. Family history: Negative. Personal history: Alternating constipation and diarrhœa for years. Discharge of blood and mucus from rectum for six months treated for hæmorrhoids. Pain only recently, burning and shooting, especially after stool. Large cauliflowerlike tu-mor beginning just above inner sphincter, and extending up two and one half inches. Admitted index finger with ease. Movable.

March 22d. Operation. Cripps perineal method, prolonged and bloody; took out three and one half inches; could not get the bowel down to suture; left open wound

to granulate.

March 23d. Patient reacting well.

March 24th. Patient had embolism or hæmorrhage of the brain, complete right hemiplegia.

March 25th. Patient never recovered consciousness, died. Peritonæum was stripped up, but not opened, therefore whatever infection occurred was extraperitoneal.

CASE II.—June 26, 1892. Mr. W. G., age fifty-four. Family history: Negative. Personal history: Always healthy until one year ago, when he began to notice some difficulty at stool. After being constipated he had attacks of diarrhoea. Began to lose blood and mucus six months ago. Had pain in back, constant desire to go to stool during day; morning diarrhea of blood and mucus; had lost flesh rapidly. Rectum normal for three inches up, where is found a large friable, nodular tumor, entirely surrounding the gut and almost occluding its calibre. Very slightly movable. Piece was removed and reported adenocarcinoma.

July 2d. Extirpated tumor by bone flap method. Patient lost little blood; only tied four vessels. Access perfect; removed six inches of the gut; end to end suture; fastened bone flap in place by silver wires; packed sacral cavity; put

large drainage tube in rectum.

July 6th. Patient had not had a bad symptom; considerable oozing following operation, but as pulse remained good the packing was not removed until to-day. Pulse 88, temperature 100.2° F.

July 10th. No complications, except sutures in gut have

given way and fæcal matter was passing through wound. July 15th. Patient was up and walking about; fistula was still wide open. Removed silver wire and found bone-

flap firmly united.

July 20th. Etherized patient, freshened wound, and su-tured fistula, stretching sphincter.

July 27th. Bowels moved yesterday and some fæcal matter came through fistula. August 1st. Fistula smaller and granulating well. Pa-

tient left the hospital. November 1st. Fistula almost healed; patient otherwise

May 27, 1908. I have seen this patient almost every year since, heard from him to-day, and he is still in perfect

CASE III .- June 27, 1892. Mrs. P., age thirty-four. Good

complexion; moderate weight.
Family and personal history was negative.

She had been treated by injection for hamorrhoids for three months. Bowels regular, but had to strain when stools were well formed. Throbbing and aching pain in rectum, especially at night. No discharge. Just inside the rectum was found a hard, round, nodular tumor, involving two thirds of the circumference anteriorly; calibre reduced fifty per cent. Mucous membrane moved over it, and it moved on the vaginal wall. Sphincter did not seem involved; it extended up about an inch and a half.

July 10th. Removed tumor by perineal dissection; sphincter dissected out and drawn aside; gut dissected up two and one quarter inches; peritonæum pushed up, but not opened; gut brought down and sutured to skin. Path-

ological report, spindle celled sarcoma.

July 12th. Patient doing well; complained of pain and pressure in the wound.

July 15th. Temperature 103° F.; redness and swelling in wound. Cut two or three sutures and let out consider-

able blood and pus, bad odor.

July 17th. Odor continued bad; slight swelling between rectum and vagina. Opened wound and found a small piece of gauze had been sewed up in wound, removed.

July 20th. Odor gone, discharge much reduced.

August 15th. Fistulous tract healed; good continence;

patient well

May 15, 1908. Patient removed to California, but I have heard from her every year; she has gained sixty pounds and is perfectly well now, almost sixteen years after opera-

Case IV.—August 10, 1892. Mr. L. K., age fifty. Family and personal history was clear. In November, 1891, patient began to be constipated, with loss of blood; four months since had severe hæmorrhage; also one four weeks later. Now has morning diarrhœa loss of blood and mucus from rectum; pain in back and is losing flesh. Bowel movements irregular and unsatisfactory. Anus normal. Deep excavating ulcer two inches up in rectum, involving the entire circumference; barely admitting finger, edges rough and nodular. Pathological report, adenocarcinoma.

August 20th. Operated. Kraske's method; prolonged

and bloody; removed section; end to end suture.

August 25th. Patient doing well.

September 20th. Patient left hospital with fistula, other-

wise in good condition.

September 1, 1903. Recurrence in situ. (Patient passed out of my service and died about eighteen months after operation.)

Case V.—October 9, 1892. Mr. J. W. S., age forty-five. Family and personal history, clear.
Fourteen years ago had fistula treated by ligature; itching ever since. Had aching, shooting pains in, and slight blood and mucous discharge from, rectum for the past four months. Bowels were regular; slight protrusion at stool. External sphincter flabby. Anus irregular, from old inci-sion. Superfluous mucous membrane in rectum; internal hæmorrhoids; on posterior wall, small, hard, nodular mass, moyable, bled easily on touch, about three quarters of an

inch above anus.
October 20th. Operation. Tumor dissected up till pedicle was formed, involving entire thickness of wall of gut and then cut off with clamp and cautery. Pathological

report, adenocarcinoma.

November 10th. Parts practically healed, patient feeling December 1, 1903. Still well; used a bougie to overcome

slight stricture. No later history.

CASE VI.—December 10, 1893. Mr. J. T., age sixty.

Family history, negative.

Three months since I removed a small polypus from anterior portion of rectum, just above the internal sphincter. Was quite well for a while, but recently had suffered from throbbing pain and discharge of blood from the rectum, especially at stool when he strained. Anus normal. At the level of the internal sphincter and extending about one inch upward, was a lobular movable growth, involving the anterior one third of circumference; did not feel like car-Section removed; pathological report, lymphocinoma.

December 13th. Removed growth, local excision. no effort to bring the wound together; prostate did not

seem to be involved

December 20th. Wound healthy, pain ceased.

December 27th. Wound healthy and filling up fast. Left

hospital and was not seen again for several months, when he returned with a local recurrence and metastatic deposits in groin and over abdomen. Died within the year.

CASE VII.-November 18, 1894. Mrs. H., age sixty-five.

Family and personal history, clear.
Patient began to notice discomfort and an occasional discharge of mucus and blood from rectum eighteen months ago. Pain not severe; treated for hæmorrhoids. Now has frequent call to stool, but difficult small passages; bowels Sphineter relaxed. Large, cauliflower growth, extending from one and one half to four and one half inches above

anus; barely admitting finger; friable, movable. Patho-

logical report, adenocarcinoma.

November 22d. Operated. Bone flap method. Gut friable and darkly congested as far up as we could follow it Did not bleed well on section. Denuded anus and invag-inated upper section of gut, suturing it to the skin; no

difficulty in pulling it down.

November 25th. Patient did well for two days, and then surgical or septic mania developed. (At this time we were informed that the patient had been subject to attacks of acute mania.) Had no sign of peritonitis; lower end of

gut was still dark and almost gangrenous.

November 27th. After distressing delirium and constantly increasing temperature, the patient died; probably from sepsis, due to gangrene of the gut, in which circulation was so imperfect.

CASE VIII.—December 1, 1894. Mr. H. L., age twenty-

Family and personal history, clear. One year ago patient had ligature operation for piles, followed by protracted ulceration; later had small hæmorrhoid excised. Suffers now; weight and uneasiness in back and rectum; frequent desire to go to stool. Indigestion and flatulence, discharged mucus and blood frequently, fæces only once a day, and then with difficulty and of very small size. Anus normal; some contraction of sphincter. Rectum; nodular, ulcerating mass two inches above the anus and extending above reach of finger, calibre the size of index finger; growth movable. Preparations for opera-tion, laxative daily and bichloride, 1 in 5,000 irrigations;

milk, meat, eggs, and rice diet.

December 8th. Operation. Kraske's method. Removed coccyx and right corner of sacrum up to the fourth foramen. Excised eight inches of the gut, entering the peritonæum; packed off latter; sutured gut end to end; packed posterior wound. (The chart and history of this case was burned in wound. (The chart and instory of this case was builted the hospital before being entered on my private books. The patient had a long convalescence, but eventually left for home with wound practically healed.) Pathological report,

adenocarcinoma.

January 5, 1905. Remained well ten years after the operation, although he had slight incontinence of fluid fæces, due to nerve impairment or former operations; the muscles were not cut in last operation.

Not heard from since 1905. Was well then.

CASE IX.-May 20, 1894. Mr. A. V., age sixty-two.

Family and personal history, clear. Not ill in thirty years till six or eight months ago, when he noticed bleeding at stool, slight protrusion; this in-creased; now has difficulty in moving bowels and a feeling of weight in rectum; very little pain. Large cauliflowerlike growth four inches up the rectum and extending be-yond the reach of the finger; not felt in inguinal fossa; bled easily. Pathological report, adenocarcinoma.

May 25th. Bone flap operation; very little hæmorrhage; tied only two vessels; end to end suture. Time, two and

one quarter hours.

June 1, 1895. Bowels moved, leakage from posterior fis-tula. Hospital records burned, but the fistula closed after four months; the patient lived until 1902, without recurrence, and died of pneumonia.

CASE X.-November 10, 1894. Mr. M. W. W., age fifty-

Family history, negative.

Well until six months ago, except for constipation. Had taken laxatives for years. Six months ago began to have frequent desire to go to stool, usually without much effect; at first noticed clear mucus; now passes mucus at early morning stool; frequent calls to stool, but only one or two real passages a day. Flatulence and loss of appetite. Some skin tabs around anus. Rectum normal to three inches. where a large, friable, cauliflowerlike mass encircled the rectum, admitting index finger; attached to sacrum, but

movable in front. Pathological report, adenocarcinoma.

November 12th. Bone flap operation. Tumor extended upward four inches; six inches resected; superior hæmorrhoidal artery clamped and cut, clamp left on. Parts united by reinforced Murphy button; wound closed except for lower one and one half inches. Peritonæum sutured; sacral

cavity packed.

November 15th. Clamp and gauze removed, considerable oozing.

November 18th. Sloughing of gut about Murphy button; removed button through posterior wound.

November 24th. Patient did well, except for large posterior fistula

December 5th. Incised anus and rectum posteriorly up

to fistula.

December 20th. Wound healed down to within one inch of anus. Complete incontinence for liquid or soft stool. Patient left hospital. Wound almost entirely healed; conti-January 25, 1895.

nence improved. November 10, 1895. Parts healed, no recurrence. In-

continence improving.

Patient living and well four years after the operation; was lost sight of afterwards.

CASE XI.—May 15, 1895. Mrs. D., age fifty-five.

Family history, negative

Well until three months ago, when she began to have pain in the rectum; this gradually increased and was worse at night. Had a lump on side of rectum. Pain no worse at stool. Loss of blood at first, none now. Constant pro-trusion. On right posterior quadrant and extending out on the buttocks one and one half inches and up into the rectum one inch was a black, lobulated mass, which could be grasped by the fingers and moved on the tissues below; not painful to touch. Above the tumor the gut seemed perfectly healthy. Specimen taken for examination; pathological report, melanosarcoma.

May 20th. Operation. Perineal excision; wide excision of growth. No attempt made to preserve sphincter, or to

bring the gut down to anus; left the wound open. June 1st. Suppuration, but granulation going on nicely. June 15th. Wound filling up; no fæcal control.

August 13th. Wound healing; patient left hospital. November 10th. Wound healed. Cicatricial narrowing

November 10th. Would headed. Cleartical harrowing prevents solid faces escaping, but no voluntary control. November 25, 1908. Patient was lost sight of, but I heard to-day that she lived until 1903, nearly nine years after the operation, and died "from tumors all over her body." Evidently a delayed metastasis.

CASE XII.-March 10, 1895. Mrs. R., age fifty-six.

Father died of cancer.

Patient had dysentery ten years ago, otherwise personal Had been constipated for forty history was negative. years; stools hard and lumpy. About one year ago began years; stools hard and lumpy. About one year ago began to have flatulence and griping pains, no diarrhoea; then came passages of mucus with crises; had been passing blood and mucus several times a day for the past five months; had not lost much flesh. Frequent desire to go to stool, but unsatisfactory. Some skin tabs about the anus and hæmorrhoids. In the rectum there was a hard, nodular these these times the court flow in the second state. lar, ulcerating tumor, surrounding the gut, two inches from the anus, extending up two and one half inches;

movable and admitted finger easily.

March 15th. Operation. Vaginoperineal method. Circular incision in front of coccyx, tumor loosened from sacrum and all around to central raphe; cavity packed with gauze. Incision in postvaginal wall, opening peritonæum at vagina; cut off one inch above anus; anal end everted; proximal end of gut invaginated and sutured to anal end with two rows of chromic catgut sutures; large drainage tube inserted, and parts allowed to retract; peritonæum closed before gut was cut off; vaginal wound closed by sutures passing through muscular wall of gut, in order to

March 17th. Posterior packing removed; drainage tube

March 27th. Small posterior fistula, through which liquid fæces escaped; otherwise well. Patient left for home. November 15, 1895. Fistula healed in about three months,

January, 1904. Patient lived seven years, and died of pneumonia. Had no incontinence, and always felt well.

CASE XIII.—July 26, 1896. Mr. R. C., age forty-one. Family history, clear, except father, age seventy, had

Personal history was clear except for prolonged constipation of six months' standing, followed by dysentery, with mucous discharge. Had frequent desire to stool; slight mucous discharge, occasionally streaked with blood; flatulence and loss of appetite. Anus normal. Nodular stiff condition of the anterior wall of the rectum two and one half inches up; area involved, one by one and one half July 29th. Removed tumor by perineal excision; posterior wall left intact; split sphincter anteriorly and left it

open for drainage.

August 5th. Pathological report beginning malignant transformation in granular stricture. Convalescence satis-

August 15th. Left for home.

January 16, 1904. Saw patient and he is still well. February 1, 1908. Patient still well.

CASE XIV.—October 30, 1896. Miss E. T., age twenty-

Family and personal history, clear.
Patient had been constipated for years, but began eighteen months ago to have frequent desire to go to stool, with passages of mucus and blood; recently passed only blood. Had lost thirty pounds in weight; bowels moved many times a day, especially in the morning; severe shooting and burning pains in rectum. Anus normal. One inch up in the rectum was an immense friable, cauliflower growth, involving the entire circumference, extending above finger

November 2d. Operated, at patient's insistence, at her own home in the country and with what instruments a country village afforded. Kraske's method. Removed eight inches of rectum, uterus, and appendages; much blood and time lost through insufficient hæmostatics, etc.
Peritonæum packed; gut sutured in sacral wound.

November 3d. Patient died from shock eighteen hours

after operation.

CASE XV.-January 20, 1897. Mr. E. P. L., age fiftyseven.

Family history, clear.

Patient gave indistinct account of syphilitic sore twentyfive years ago, but no constitutional phenomena. past year he had suffered from alternating diarrhoea and constipation; passage of mucus occasionally tinged with blood; morning stool; practically no pain. Flatulence and indigestion. Bowels only move now by laxatives, and then like water. Anus normal. Rectum normal. Sigmoidoscope showed granular ulcerating mass seven and one half inches from the anus, almost completely occluding gut.

Preparations for operation, salines and bichloride irrigations, I in 6,000. Diet, milk, eggs, white meats, soups, rice,

and white bread for one week.

March 13. 1897. Incision outside left rectus. Tumor could not be brought out of wound; gut tied twice below tumor and cut off above rectosigmoidal junction. excised and colorectostomy performed, i. e., the upper end of the rectum was closed and the colon was carried down through a slit in the anterior wall of the rectum, and held there by strong ligatures passed through the four quadrants of the sigmoid, and carried out through the anus and wound around forceps, acting as a windlass. Abdominal wound closed with gauze drain down to point of invagination of sigmoid into rectum.

March 20th. Bowels moved, and for a time it seemed that a small fæcal fistula was present, but the odor from the fistulous tract was the only evidence of this. April 25th. Opening at junction with sigmoid so con-

tracted that bowel movements were difficult. Inserted a long pair of hysterectomy forceps, one blade in the rectum and one in the colon, to crush sæptum and enlarge the

May 1st. Pulled forceps away too soon; considerable hæmorrhage followed; controlled by packing.
October 1, 1902. Committee of the New York Medical

Association examined patient and reported him absolutely well.

February 27, 1908. No recurrence. Patient well. CASE XVI.-December 20, 1897. Mrs. W. S. A., age

Family and personal history, clear.
Patient formerly suffered from "itching piles," but these disappeared. Constipation increased for three years; desire to defæcate without result for two years; no pain; slight mucous discharge. Anus normal. Rectum slightly catarrhal; prolapse of the sigmoid into the rectum. Small, hard, nodular tumor in fold of prolapsing sigmoid, not to

be felt with finger, but base felt soft to forceps.

December 23d. Operated. Snared off tumor; cauterized base with pacquelin. Pathological report, papilloma with

malignant transformation.

Convalescence uninterrupted. Saw the patient three years later, no recurrence.

Case XVII.—January 1, 1898. J. D., age forty-two. Family and personal history, negative. Patient had been constipated for years. Began six months ago to have desire to go to stool without results; this increased. Began to pass mucus five months ago and blood two months ago. Lost very little flesh, but felt weak. Flatulence and loss of appetite. Bowels move now eight Flatulence and loss of appetite. Bowels move how eight or ten times a day; morning diarrhoæ; very little pain. Marked hæmorrhoids. Large, friable, cauliflowerlike mass filling rectum, beginning three inches up; movable; finger could be passed through it, and by pulling down the top of the tumor could be reached. Pathological report, adeno-

January 5th. Removed growth, Kraske's method; very difficult to get bowel down, finally had to suture it to sacral wound. Peritonæum sutured. Postanal wound left open

for drainage.

January 20th. Patient doing well, except for constant

discharge from sacral anus.

February 15th. Patient practically well except for incontinence, which annoyed him so much he begged to have inguinal anus made, such as a man in the next bed had.

Operated to-day, February 18th. Infection occurred and patient had peritonitis.

February 20th. Patient died last night.

I should never have done the second operation. This death should not be counted in mortality of extirpation.

CASE XVIII.—February 26, 1898. Mr. J. P., age forty-

For several years patient had noticed a small lump in the rectum. which had been steadily growing; caused no pain beyond an uncomfortable straining at stool; did not come outside. Passed no blood or mucus; had several stools a day, but only one that amounted to anything. Anus normal. In the rectum about two and one half inches up was a hard, nodular tumor, about the size of a horsechestnut, pedunculated, with very little induration at the base; was attached to the anterior wall, just to the left of the

March 1st. Operation. Sphincter split open; posterior parts brought to one side; tumor resected, with mucous membrane, for about one inch in diameter about its base; edges brought together and sutured. Posterior wound left open for drainage. The sutures did not hold perfectly, leaving a granulating spot. He left the city in about four

weeks, felling well.
Pathological report, adenocarcinoma.

His physician reported him well two years later.

CASE XIX.-July 27, 1898. Mr. J. A. P., age forty-one. Pain in left side, alternating diarrhoea and constipation,

occasionally blood.

Cylindrical tumor in left iliac fossa, not particularly hard, increased in size during periods of constipation, movable, and appeared about four inches long. Patient had atropic catarrh of the rectum; one small granulating ulcer on left posterior aspect which appeared to have formed re-cently. Sphincter contracted. Sigmoidoscope passed for eleven inches and was arrested by stricture or tortuosity (not able to make out which on account of rigid condition of patient)

July 30th. Operated. Tumor in the left inguinal fossa proved to be cancer of the sigmoid; resected; Murphy

button, removed seven inches

August 5th. Peritonitis developed and patient died to-Sloughing and leakage around button shown by autopsy

CASE XX.—September 26, 1898. Mr. H. D., age twenty-

Family history, negative.

When twelve or thirteen years of age patient noticed a little blood in stool; no pain at that time. Six months ago had an attack of griping pain all over the abdomen, but more particularly over the left side. Diarrhoa began about that time; it increased until three months ago, when he was admitted to Roosevelt Hospital, and there treated locally for a time; he appeared to improve, and was discharged. All the symptoms recurred; he passed blood and mucus with stools. Anus normal. Four and one half inches up the rectum a large nodular mass was movable and without pain; the top could not be reached. Pathological report, adenocarcinoma.

October 1st. Bone flap operation. Resection of about

seven inches; end to end union. Bone flap sutured in posi-tion. Not much hæmorrhage. Peritoneal wound packed. Patient made good recovery from operation.

October 5th. Packing removed.
October 8th. Bowels moved. Posterior fistula, with in-

fection. Otherwise no complications

January 17, 1899. After prolonged infection, and some stricture at point of union, the patient finally recovered. Left the hospital feeling comparatively well. Heard from two years later, after he returned to Russia; he was then feeling well. No further report.

CASE XXI.—November 7, 1898. Mrs. H., age thirty-one.

Family history: Tuberculosis. Personal history: Typhoid fever some fifteen years ago, followed by stomach and bowel trouble. In past two or three years had had hæmorrhage from bowels and stomach. Was constipated and passed mucus and blood at stool; no pain with passage, no exhaustion afterwards. Physical examination negative. Anus normal. Hard nodular growth at junction of rectum with sigmoid arrested speculum.

November 12th. Bone flap operation. Adhesions of the sigmoid to broad ligament, difficulty in bringing it down. Did resection of five inches. Circulation in gut good, tied middle and right lateral sacral arteries; closed peritoneal cavity by sutures. End to end union.

November 15th. Patient progressing well. Temperature,

101° F.; pulse, 110. Pathological report, adenocarcinoma. November 21st. Bowels moved, so far no leakage.

November 30th. Progress satisfactory, slight leakage when stools are thin, otherwise none

December 20th. Leakage stopped; fistula persisted, four inches deep. Patient left for home.

January, 1900. Reported herself well. Not heard from

CASE XXII.-March 28, 1899. Mr. W. F. D., age sixty. Family history, negative.

Personal history: Had had fair health; three years ago noticed protrusion at stool, with soreness which was relieved by salve. Twelve months since noticed frequent desire to stool, preceded by wind; stool small; morning diarrhea. For several weeks had had blood before stool. No tympanites. Stricture two and one half inches up the rectum, soft, and friable, bled easily on touch. Some induration in left inguinal fossa. Odor not distinctive.

April 2d. Adenocarcinoma removed by perineal method; gut brought down and sutured to anus; removed four and

April 15th. Patient made uneventful recovery, although the union was not primary, he left the hospital with granulating area in anus

March, 1903. Physician reported patient in fine condi-

February, 1908. No reply to letter. His physician had

died in the meantime, so I cannot trace him. CASE XXIII.-April 7, 1899. Dr. D. O. K. age fifty-

Family and personal history clear. Not constipated except when taking medicines. About ten years ago, after an attack of dysentery (?), began to have morning diarrhœa. Every morning about six, regardless of time of retiring, was called to the closet and had two or three mucus, watery movements; after this had a fairly comfortable day. Large nodular tumor, barely admitting finger, began three inches up and extended about two and one half inches. By dragging it down could reach healthy tissue above. Adenocarcinoma.

April 22d. Bone flap operation. Tumor removed. Peritonæum opened and closed before entering the gut; end to end suture; very little hæmorrhage; sutured flap back in position. Posterior drainage.

April 15th. Patient doing well; removed drainage. April 20th. Some infection and leakage from point of

junction, but nothing alarming April 30th. Sacral cavity closing down and fistula closing. May 15th. Patient left for home, well, except for small

November, 1904. Patient remained well. April 30, 1908. Reported that he is well.

CASE XXIV.-September 12, 1899. Mr. H. G., age thirty-

Family history, negative.

Personal history: Patient had never been ill except from the diseases of childhood. Sex months age while on a

drinking bout, he passed blood from the rectum, subsequently blood passed almost every day; constant diarrhœa; scarcely any pain, but a feeling of malaise and low spirited. Three weeks ago had a severe attack of colic, attended by vomiting; lasted about five days, followed by headache. loss of appetite, constipation, and discharge of mucus streaked with blood. Anus normal. Nothing could be felt in the rectum with the finger. Kelly's proctoscope showed an obstruction eight inches above the anus. Patient refused operation.

April 4, 1900. Patient readmitted, so much distended by acute intestinal obstruction that an examination could not

be made. Made right artificial anus.

April 26th. Patient recuperated rapidly after the artificial opening, but was losing flesh, owing to a continued fluid passage. Opened the abdomen again and found a large cancer of the sigmoid, firmly adherent to the brim of the pelvis and to the bladder. Conditions considered inoperable. The ileum was brought down and inserted into the rectum; and the artificial anus closed. The patient made a good recovery and improved rapidly in strength, going home from the hospital in about three weeks after opera-

We have no further report of him, but I suppose he died in a short time, owing to the enormous growth.

CASE XXV.-December 4, 1899. Mr. T. H., age sixty-

Family history, negative. Patient had always been well until three months ago, when he began to have pain in the rectum, especially when the bowels moved; was constipated; passed blood and mucus several times a day, but fæces only once. Had frequent urination. Anus normal. Two inches above the margin of the anus a large, boggy, bulging mass, ulcerating and involving the entire circumference of the gut was found, extending up two and one half inches. Pathological report, adenocarcinoma.

December 11th. Operated. Bone flap method. Mucous membrane dissected from the lower segment of the rectum; the sigmoid was dragged down through the anus and sutured to the skin margin; posterior drainage. Four and

one half inches removed.

December 15th. No complications.

January 12, 1900. Patient left the hospital, with a small posterior fistula.

April 17th. Patient returned. A small nodular recurrence on the edge of wound. Removed under general Removed under general anæsthetic. Patient left the hospital one week later well, and has

never been heard from since. CASE XXVI.—October 4, 1900. Mr. T. McM., age forty-

Family history, very good.
Personal history: Formerly drank considerably and smoked excessively, but for three years past has done neither. Bowels had always been regular. For some time had had pain in bowels before movement. Did not notice what passed after these attacks. Constipation began last June; took laxatives; desire to stool, but without success.

Morning diarrhoa. Could just feel hard nodular mass high up in rectum.

Diagnosis: Cancer at junction of rectum with sigmoid. October 11th. Bone flap operation. Bowel tore across before peritonæum was closed. Superior hæmorrhoidal artery torn in loosening attachments from sacrum; unusual hæmorrhage. Notwithstanding this, patient returned to room in fair condition, and five hours later had a pulse rate

October 12th. The patient did well until 12 m. to-day, when he began to get restless; his temperature rose to 110° F., and he died about 11 p. m. Autopsy showed gangrene of lower six inches of sigmoid, which had been brought down; evidently due to tearing off of the inferior mesenteric artery.

CASE XXVII.—April 12, 1900. Mr. W. W., age fifty-

Family history, negative.
Patient had had hæmorrhoids for twenty years, which bleed at stool. Five years ago noticed a mass come down at stool; it was very red. At about the same time noticed a profuse discharge of mucus and loss in weight. week- ago had a piece of the mass removed, about the size of a small apple, since which time the discharge had become

flatulence for the past six months; had always been constipated. Anus normal. One and one half inches up the rectum was a hard ulcerating mass, with one polypoid excrescence, entirely surrounding the rectum, adherent to the prostate, but movable posteriorily. Section showed adenocarcinoma.

April 17th. Bone flap operation. Removed six inches of the rectum and both lobes of the prostate; mucous membrane dissected off from sphincter and upper end of the gut brought through and sutured to cut margin of anus.

April 21st. Patient had no complications, except difficulty in urination. Small posterior fistula at sight of opera-

tion. Prostate removed not carcinomatous.

May 1st. Patient doing well; some cystitis and posterior

fistula.

May 23d. Under general anæsthetic posterior fistula was split open into anus, as the latter was somewhat contracted; anterior wall of rectum was found to have united perfectly; posterior wall was broken down, leaving a large cavity between the rectum and sacrum, in which a mass of hard fæces had collected.

June 30th. Under packing and local irrigation the parts

have healed; patient had almost complete continence and

was well, with the exception of a mild cystitis.

January 10, 1901. Patient had trouble with bladder for

six months, but this is also relieved.

Remained well and visited me from time to time until November, 1905, when he began to have great trouble with his bladder. Cystoscopy revealed much inflammation—probably recurrence (?) in the bladder; this condition continued to grow worse until it caused his death in January, 1907, nearly seven years after the extirpation.

· CASE XXVIII.-March 15, 1900. Mrs. B. P., age fortytwo.

Family history, negative.

Began to menstruate at thirteen; she had always been regular, but with much pain. Had a child born nine years ago without much difficulty; three years ago a second child was born; at this labor she was badly torn, since which time she had suffered from pain in her back and severe dragging sensation in abdomen. She had suffered from chronic constipation. One year ago the left ovary was removed; five months ago she was operated upon for hamorrhoids, obtaining very little relief; since that time she had suffered with increased constipation, with frequent desire to go to stool, without effect. Anus normal. Three and one half inches up the rectum was a large, hard, nodular, ulcerating growth. Pathological report: On rectal specimen, adenocarcinoma; on section from cervix, epithelioma

November 26th. Laparotomy, removing remaining tube. ovary, and uterus. The gut was loosened by the mesosigmoid and mesorectum being cut, and a large gauze pad inwound closed. Patient then put in lithotomy position and the rectum and tumor excised, by vaginal method. End to end suture; large rectal tube introduced; an opening made between the rectum and coccyx into retrorectal space and drainage tube introduced; peritoneal floor closed through vagina.

April 1st. Vaginal packing removed; seemed to be doing well. There had been some fæcal movement through the rectal tube; slight discharge from posterior drainage.

April 10th. Barring slight posterior fistula, patient was

April 10th. Sarring signt posterior istula, patient was doing very well. Anterior sutures had all held.
April 12th. Slight discharge from posterior fistula.
April 19th. Fistula remained; no more discharge. Pa-

tient left for home to-day. April I, 1902. Patient reported herself well; continence

June 1, 1905. Saw patient's physician, who reported her

well. No later news. CASE XXIX.—February 28, 1900. Mr. L. M. W., age

Family history, negative.
Patient stated that he had suffered from stricture of the rectum since infancy. Six years ago had inflammation of the bladder and prostate. A one months ago was operated upon for hamorrhoids; before this had bloody stools, with

Present symptoms: Diarrhoea; loss of blood and mucus; pain in rectum and back. Anus irritated and inflamed. One and one half inches within the margin of the rectum was an ulcerating, inducated rodule, extending upward two and one half inches, at which point the calibre was almost closed and the induration was very great.

March 1st. Extirpation, bone flap method. Removed lower six inches of the rectum; could not get bowel down low enough to restore normal outlet; made sacral anus. Peritonæum stripped off, but not opened.

March 1st. Patient had considerable outlined to the patient had considerable outlined.

March 4th. Patient had considerable oozing, otherwise

doing well.

March 10th. Continued to do well; some little infection below artificial anus, but it was superficial.

March 21st. Wound entirely healed; fæcal discharge from rectum. Patient left for home. Pathological report, adenocarcinoma.

Patient died the following year from pneumonia; no

recurrence.

CASE XXX.-January 9, 1900. Mr. R. N. G., age thirty-

Family and personal history were negative. Patient had had good health until two years ago, when he noticed blood in stool; it had gradually increased, with sharp pain in rectum. Painful urination. Anus surrounded with ulcerating skin tabs, with a granular mass protruding in the centre. Patient unable to bear an examination; in a very low condition

January 11th. Etherized and examined; found a large carcinomatous mass following up the rectum, immovable, involving the prostate, wall of the bladder, and all surrounding organs. Did inguinal colostomy, Maydl method.

Cancer considered inoperable.

After refusing to operate further, I February 1st. yielded to this patient's importunities and undertook to re move his rectum. Bone flap method employed. Removed ten and one half inches of the rectum, entire prostate, prostatic urethra, and part of the posterior wall of the bladder between the two ureters. Sutured the bladder together; as the patient was too weak to finish the operation, parts were packed and saline infusion made, and he was

February 20th. Patient improved so much that we undertook to close up the bladder; edges freshened and brought well together; membranous urethra brought back, and sutured into the neck of the bladder, a large rubber eatheter being passed through from the meatus to the bladder and

sutured. Parts brought well together.

March 18th. A fair result had been obtained, while the patient had a perineal fistula, losing considerable urine; nevertheless, he passed most of the urine from the meature. Tumor showed no evidence of recurrence. He left the hospital to-day, a comparatively well man. He was taking 32 grains of morphine when he entered, and none when

April, 1907. This patient lived over seven years, supporting his family by bookkeeping, and died from Bright's disease in February, 1907. His doctor reports there was

no recurrence

CASE XXXI.—September 21, 1899. Mrs. M. N., age sixty.

Family history was negative.

Patient had always been strong and healthy. About three months ago she began to have a throbbing, heavy, aching sensation at the lower end of the rectum; a small swelling soon appeared, and this extended toward the buttocks ever since. Had always been constipated. Constant pain and flatulence. Moisture, but no blood or pus and no protrusion. Irregular swelling on the left posterior quadrant of the anus; skin moved over it; seemed to involve the sphincter and deeper tissues; extended up into the rectum about one inch; mucous membrane and mucocutaneous membrane over the tumor was black. Melanosarcoma.

September 24th. Perineal excision; removed three inches of the gut, and sutured end in anus. The wound, when extended out, into the huttonke, was collegated.

which extended out into the buttocks, was only partially

closed, and drained.

September 30th. Gut united primarily; wound in the buttocks so healthy there was scarcely a drop of pus. October 10th. Bowels moved regularly; no pain; but-

tock wound nearly healed.
October 1, 1900. Patient still perfectly well.

October I, 1900. Patient still perfectly well.
April 2, 1902. Patient still perfectly well.
April, 1906. Letter from patient's daughter states she
died from recurrence in the abdomen. September, 1903.

CASE XXXII.-May 7, 1900. Mrs. L. M. B., age thirty-

Family history, clear

Constipated since she had inflammation of the bowels,

fifteen years ago. Stools had depression in them. bowels were full had severe pain in the left iliac and hypogastric region; this had been increasing recently. Diffi-culty in urination. Hard, slightly nodular tumor at junc-tion of rectum with sigmoid, attached to sacrum and constricting the calibre to the size of a large lead pencil. Scirrhous carcinoma

May 12th. Operation; bone flap method. Had considerable hæmorrhage from superior hæmorrhoidal artery just above the tumor; had to take out about four inches of the sigmoid above growth before sufficient circulation was found to justify suturing. Hæmorrhage controlled by clamp on superior hæmorrhoidal artery (left on three days).

End to end suture; closed peritonæum.

May 20th. Patient doing well; considerable discharge and slight fæcal leakage posteriorly.

June 1st. Convalescence uninterrupted.
July 5th. Patient left hospital, with small fistulous tract.
Fæcal leakage gone. October 2d. Everything healed; very slight constriction

at suture.

April 10, 1901. Still well; constriction practically gone, January 10, 1908. No recurrence; quite well.

CASE XXXIII.—April 2, 1900. Mrs. H., age forty-four. Mother died of cancer; father of tuberculosis.

Patient had always been constipated; was operated upon for hamorrhoids in 1891, said to have had stricture. Since 1894 had a dull, aching pain in the back, not influenced by stool. Bled only once in a while; discharged membranous mucus sometimes tinged with blood. Discharge had never mucus sometimes tinged with blood. Bischarge had involuntary, ceased since operation in 1891, purulent and involuntary. Continence for the past year also grew less and less. No external manifestations. About three inches up a hard, leathery contracture, movable but not nodular, was felt.
No specific history. Pathological report, scirrhous cancer.
April, 1900. The detailed history of this case was lost in

the hospital fire. A bone flap operation was done and about seven inches of gut removed. Hochenegg invagination method. Was in the hospital about five weeks; had a small

fistula, but recovered in good time.

Remained well over two years, and was then lost sight of. CASE XXXIV .- May 27, 1900. Mrs. B. S., age thirty-five.

Family history was good.

Personal history: At twelve years of age began to have Personal history: At twelve years of age began to have lymphatic enlargements. Recently complained of pain in rectum and griping pain in bowels. Pain in rectum first, then in abdomen. Passed mucus since one year ago, with after feeling of exhaustion. Mucus discharge sometimes every day, sometimes several days apart. May 20th. Nodular growth surrounding rectum, friable, admitted index finger. Began two and one half inches, extended one and one half inches, very movable. Pathological records admorational.

report, adenocarcinoma.

Tumor removed; vaginal route; very easy, June 4th. but did not clear sacral space so satisfactorily as bone flap. Postanal drainage.

June 7th. Patient did well, but had temperature of 102° F., indicating infection. Packing removed, a large amount of bloody serum discharged, drainage tube

Temperature reduced to 100.5° F. Patient June 8th. very tender about rectum and vagina; free purulent

discharge Temperature 99.2° No complications. June 12th.

Bowels moved yesterday; leakage from posterior wound.

June 20th. Patient walked about the floor to facilitate drainage; no change in condition.

July 1st. Leakage less; fistulous tract smaller. August 1st. Patient left hospital with small fæcal fistula. Moved and left no address.

CASE XXXV.-January 25, 1901. Mr. C. N., age fifty-

Family history was negative.

Personal history: Began to notice pain in rectum two years ago; diarrhea soon developed, and grew worse. Patient had had no treatment. Much flatulence and indigesgestion; had lost very little flesh; color good. Anus normal. Three inches above the margin of the anus there was a control of the color and extended the color and hard, friable tumor, entirely surrounding the gut, and excluding the passage so that one could only introduce a small probe. Under anæsthetic the finger was pushed through, and the upper limits of the tumor were found at about four and one half inches. The tumor was movable except at a level with the prostate, where it seemed to be attached. Pathological report, adenocarcinoma. Salines and

peroxide irrigations ordered.

January 30th. Operated. Perineal excision; six inches of gut removed. Attachment to prostate was only inflammatory, and this organ did not seem involved in the growth.
Peritonæum sewed up, wide posterior drainage. Musculature of rectum sutured about gut. Mucous membrane attached to skin around the margin of anus. Rectum held back in sacral cavity by perisacral suture; very little

February 5th. Primary union, except in the posterior commisure, where packing was introduced; very little

discharge.

February 10th. Two or three of the sutures around the repruary forn. Iwo or three of the shires around the margin of the anus had given away, leaving some granulation. Gut not retracted; perisacral suture removed.

February 25th. Patient discharged; all parts healed except a little granulation at posterior commisure.

Attended clinic for several months, then disappeared, and

has not been heard from since.

(To be continued.)

JAUNDICE DUE TO DISEASE OF THE BILIARY AND PANCREAS PASSAGES.

With Report of a Case of Cancer of the Pancreas and Liver in Which There Was an Absence of Hydro-chloric Acid and Pepsin from the Stomach Contents.*

BY JOHN J. GILBRIDE, A. B., M. D., Philadelphia,

Instructor in Diseases of the Stomach and Intestines, Philadelphia Polyclinic, Assistant Demonstrator of Votoniy at the Medicochirurgical College.

Jaundice, like albuminuria, is only a symptom. However, the correct interpretation of the peculiarity of this symptom frequently enables one to make a correct diagnosis, and as it is in obstructive jaundice that difficulty in diagnosis is most frequent, I wish to call attention more particularly to the two most common causes of this condition, namely, gall-

stones and pancreatic disease.

The association of diseases of the pancreas with gallstones has been pointed out by a number of observers, and in order that we may better understand the various manifestations of the subject under consideration, let us take a short review of the anatomy of the biliary passages and structures in juxtaposi-tion thereto. The right and left bile ducts from the liver unite to form the hepatic duct which in turn is joined by the cystic duct to form the common bile duct. The common duct may be divided into four parts, supraduodenal, retroduodenal, pancreatic, and intraparietal. According to Helly, the pancreatic portion of the duct passes through the tissue of the head of the pancreas in about sixty-two per cent. of individuals, and it passes in a groove behind the gland in the remaining thirty-eight per cent. Therefore in diseases involving the head of the pancreas, the common duct will be pressed upon in the majority of instances. The termination of the duct is also of particular interest on account of its ending in common with the duct of Wirsung in the ampulla of Vater. This arrangement of the termination of the pancreatic duct forms the one weak point in the anatomy of the pancreas. The accessory duct of the pancreas, or duct of Santorini, is a variable structure and opens into the duodenum at from 0.75 to s inch above the opening of the diverticulum of Vater. The ducts of Santorini and Wirsung usually (ninety per cent., Opie) communicate in the substance of the gland, but the former is impervious in $(A_{i,j})_{i,j} = \{(A_{i,j})_{i,j} \in A_{i,j} \text{ and } (A_{i,j})_{i,j} \in P_{i,j} \cap P_{i,j} \cap P_{i,j} = 0\} \quad \text{for } i \in M_{i,j}$

about one fourth of the cases. The triangular area between the duct of Santorini above the duct of Wirsung below and the duodenum externally is termed the triangle of pancreatic inflammation. Mr. Snyder Philips believes that catarrhal jaundice, especially the epidemic form, is probably due to pancreatic disturbance, and is similar to such inflamma-

tion of the parotid gland as mumps. The most frequent cause of obstructive jaundice is stone or stones in the common duct. The obstruction may be complete or partial. It is usually partial, although the block may be complete at first, as changes soon take place in the wall of the duct that permit of the escape of bile into the intestine, and the jaundice which was gradually getting deeper now shows a variation in depth of tinge, and a change of color may be noted between morning and evening. A ball valve effect may be produced by the intermittent blocking of the duct by the stone, as pointed out by Finger. This will show itself by the change in depth of the jaundice and the appearance intermittently of bile in the fæces, etc. According to Moynihan, complete obstruction of the common duct due to stone rarely persists longer than three months. Jaundice is always present in chronic obstruction of the common duct, whether the obstruction is due to stone or otherwise. Jaundice, however, as a symptom of gallstones in general is regarded as rare by many writers. Murphy states that jaundice is present in only ten per cent. of cases, whereas Deaver (American Journal of the Medical Sciences, January, 1908) says that jaundice is, or has been, present in about three fourths or, to be exact, 69.9 per cent. of his cases of gallstones. Jaundice first shows itself in the sclera of the eye, or it may be present in the skin of the abdomen and not noticeable in the parts exposed to the sun. A painstaking history and careful examination is sometimes necessary to show that jaundice has been or is present. The writer has on several occasions elicited a history of jaundice from patients after making a diagnosis of gallstones.

If a case of common duct obstruction due to stone is kept under observation for a few weeks there will usually be found the symptoms of infection. The liver is nearly always enlarged in the early stages of chronic obstruction of the common bile duct. The gallbladder is not palpable in the majority of instances as it is unable to distend on account of its thickened walls and adhesions due to repeated attacks of cholecystitis. Courvoisier pointed out that when persisting jaundice was associated with distention of the gallbladder, the cause was in over ninety per cent. of cases an obstruction of the common duct from without. Courvoisier, therefore, gave us this law that bears his name: "In cases of chronic jaundice due to blockage of the common duct a contraction of the gallbladder signifies that the obstruction is due to stone; a dilatation of the gallbladder, that the obstruction is due to causes

other than stones."

Several cases of intermittent tumor formation due to alternate distention and emptying of the gallbladder have been recorded. This condition was caused by the ball valve effect of stone in the common duct. A case of this kind came under my observation a short time ago in the person of a physician's father in law.

Moynihan says, of all the conditions which simulate calculous obstruction of the common duct, probably none is so difficult to distinguish as chronic pancreatitis. The frequency of the association of the two diseases is well recognized and we are indebted to Reidel, who first called attention to this fact. Mayo Robson says that pancreatitis was present in sixty per cent. of his cases of stone in the common duct. The Mayos (Journal of the American Medical Association, April 11, 1905) found pancreatitis in 18.6 per cent, of their cases of common duct obstruction due to stone as against 4.45 per cent. when the gallbladder only was involved. The Mayos do not dispute the correctness of Mayo Robson's observation, and attribute his higher percentage to a more careful analysis of the fæces and urine. Mayos also state that eighty-one per cent. of the cases of pancreatic disease were due to or accompanied by gallstones. In about eightyfive per cent. of the cases of pancreatitis the head of the gland showed evidence of inflammation.

If the chronic pancreatitis be due to gallstones, there will usually be a previous history of the symptoms of this latter disease, associated with tenderness in the epigastrium and some fullness above the umbilicus; loss of flesh soon becomes marked, and the pain usually passes from the epigastrium around to the left side, to the scapula or left kidney region. Jaundice which is present deepens as the head of the gland enlarges, and increases the pressure on the common duct. Dyspepsia symptoms are marked. If the pancreatitis is due to other causes than gallstones, as infection from a duodenal catarrh, ulcer of the duodenum, infection of influenza, typhoid, etc., the onset may be more gradual and the gallbladder becoming distended may give rise to a suspicion of the presence of malignant disease of the head of the pancreas, which the rapid loss of flesh tends to confirm. In a patient with a thin abdominal wall and in whom pain and tenderness do not cause rigidity of the recti muscles, one may be able to palpate the swollen pancreas.

Jaundice is not present in all cases of disease of the head of the pancreas, as it will be remembered that the common duct passes behind the pancreas in thirty-eight per cent. of all cases. The stools are frequently bulky, offensive, pale in color, greasy, and of acid reaction. Constipation and flatulency may be present at the beginning. A chemical and microscopical examination of the fæces and urine is of considerable value in the diagnosis of disease of this organ. In pancreatic disease the fat in the fæces is usually greatly increased, with an excess of the neutral fat, in contradistinction to an increase in the fatty acids when the biliary passages only are involved. The detection of a large amount of undigested muscle fibre with nuclei intact in the fæces, is believed by Schmidt and others to be of value in establishing the presence of pancreatic disease when gastric and other diseases which affect the digestion of meat are excluded. A prompt and positive reaction following Sahli's test is also thought to be of some significance in showing that the pancreas is performing its function. Cammidge's "pancreatic" recation in the urine has been of considerable value in diagnosticating pancreatic disease in the hands of those skilled in its performance. Opie found a "fat splitting" ferment in the urine of one case of hæmorrhagic pancreatitis. Other tests for determining the functional activity of the pancreas have also been brought forward.

Cancer is the most common new growth of the pancreas, and it occurs in the head of the glands in sixty-two per cent. of cases (Robson and Cammidge). The onset is gradual and usually painless. There is a general failure of health, and when jaundice supervenes it becomes absolute and unvarying. The jaundice may become almost black. Movnihan says that the jaundice of malignant disease is more of a greenish hue in contrast to the golden yellow color of nonmalignancy. The jaundice was of a greenish tinge in two cases of cancer of the head of the pancreas that came under my observation recently. The gallbladder is nearly always distended, and may attain a large size in those cases. The liver also enlarges from biliary stasis, but no nodules are to be felt as is usually the case in cancer of this organ. In some instances the enlarged, hard, nodular pancreas may be palpable. The clay colored stool, absence of bile from the fæces, with an increase in the neutral fats, etc., also hold good here. According to Robson and Cammidge the improved "pancreatic" reaction is negative in seventy-five per cent, of those cases, but it is more or less marked in the remaining twenty-five per cent.

Cancer of the pancreas not infrequently follows cancer in other organs, and pancreatic symptoms may be the first to suggest the presence of the disease. Other diseases that must be distinguished from cancer of the pancreas are cancer of the liver and cancer of the common or hepatic ducts. Jaundice may also be produced occasionally by adhesions in gastric or duodenal ulcer, enlarged glands pressing upon the ducts, aneurysm of the hepatic artery, loose kidney, gastroptosis, etc. In these latter conditions jaundice is usually not absolute, except in cancer of the common or hepatic duct; the pancreatic symptoms being absent. Jaundice is present in about half the cases of cancer of the liver. Analysis of the gastric contents following an Ewald test breakfast may be of value in making a diagnosis, as it has been shown by Moore, Alexander, Kelly, Roaf, and others that free hydrochloric acid may be diminished or absent in cancer situated in other parts of the body, such as the breast, uterus, tongue, etc. I found an absence of both free hydrochloric acid and pepsin in a patient with cancer of the pancreas and liver.

CASE.—P. F., male; age fifty-four; stone mason; born in Ireland; seen in consultation with Dr. R. T. M. Donnelly, Philadelphia, January 23, 1908.

Previous history and family history were negative.

Present condition began in September, 1907, when the patient complained of gastric distress, mostly after eating. His appetite was fair, but even after eating ever so little he would have a sensation of fullness and weight in the stomach, belching, and enlargement of the abdomen. The symptoms were gradually becoming worse, and he consymptoms were gradually becoming worse, and he consulted Dr. Donnelly on November 13, 1907. At that time the liver was not appreciably enlarged. There was no tenderness over the stomach, liver, or gallbladder. He was losing weight and strength. On December 12th a pleurisy losing weight and strength. On December 12th a pieurisy developed on the left side posteriorly, confining him to bed for five days. Jaundice appeared in the conjunctiva about the middle of December. This gradually became deeper and was unvarying. There was a tendency to diarrheea the first few months of his illness, but the bowels later became costive; the stools were hard and "puttylike." and a movement was had only by taking medicine. On January 8, 1908. he had cramplike pains in the right upper abdomen, lasting

about eighteen hours, followed by a soreness for three or

about eighteen hours, followed by a soreness for three or four days. When I first saw him he was complaining of constant severe pain in the epigastrium. There had not been any vomiting. He had been losing considerable weight since the early part of December, 1907.

Physical examination: A large, strongly built, fleshy man; weight probably two hundred pounds. Jaundice was present in the skin and conjunctiva. The color of the former was a dark, dusky appearance, while the latter was of a greenish hue. The tongue was thick and coated; teeth were in good condition. Breathing was accelerated. teeth were in good condition. Breathing was accelerated, due to abdominal distention with gas. Temperature and pulse were normal. Examination of lungs and heart were Abdomen was considerably distended; abdominegative. Abdomen was considerably distended; abdominal wall thick; some free fluid was present in the flanks. Liver dullness began at the fourth interspace in the right nipple line, and its lower border, which was sharp and somewhat harder than normal, was palpable just above the umbilicus, but no nodules could be felt. There was no pain or tenderness in the region of the galbladder, nor was the galfbladder palpable. A thick abdominal wall made palpation difficult. The outline of the stomach was not interested in the palpable. Physical examination of the stomach was not increased it injuries or spleen not palpable. Physical examinacreased; kidneys or spleen not palpable. Physical examination was otherwise negative.

The stools were clay colored, very offensive, of medium consistency, and not very greasy. Bile was absent; no occult blood. The urine contained bile; no sugar or

Gastric contents: One hundred cubic centimetres of contents were aspirated one hour after an Ewald test breakfast, and showed an absence of free hydrochloric acid; pepsin was also absent (Metts's method); no occult blood; no lactic acid or Oppler-Boas bacilli. Total acidity, 0.10.

Blood: Hæmoglobin, 90 per cent.; red blood corpuscles, 4,800,000; white blood cells, 7,400.
Diagnosis: Cancer of the liver, with complete obstruction of the common or hepatic duct. From the character of the stools I thought that the pancreas also was probably involved.

The great distention of the abdomen was embarrassing to the lungs and heart, and the patient died suddenly on

January 31, 1908.

Autopsy: Moderate amount of free fluid was found in Autopsy: Moderate amount of tree fluid was found in the abdomen. There was a cancer of the pancreas and liver with involvement of right free border of lesser omentum. The glands along the common duct formed a chain of hard nodules. The stomach and intestines were normal. There were no gallstones. Gallbladder was distended, but healthy in appearance. The primary growth was in the pancreas

The pleurisy in this case was due to involvement of the diaphragm, and the attacks of cramplike pain resembling those of bilary colic were probably due to pressure from without upon the common duct, as attacks of this kind are occasionally met with when the common duct is pressed

upon from without.

1034 CHESTNUT STREET.

A DERMATITIS DUE TO THE IRRITATING EFFECT OF METOL.

BY NATHAN T. BEERS, M. D.,

Brooklyn, N. Y.,

Attending Definite logist to the Methodist Episcopal (Seriev) Hospital and the Swedish Hospital, Brooklyn, N. Y.

A careful search through the literature of medicine brings to light the report of but one case of this affection of the skin, while the textbooks make no mention of it in any way. It seems rather surprising that the affection has escaped notice at the hands of the profession, since among professional, and even amateur photographers, metol poisoning, as the disease is commonly known, has been recognized and thoroughly dreaded for many years.

In the British Medical Journal of December 31, 1904, Dr. Arthur Storrs reports the case of a man of

fifty years, a photographer, whom he found in bed suffering from a general erythematous eruption, his hands swollen and erysipelatous in appearance. While the rash was general, it was only slightly in evidence on the patient's legs, and faded off into a mild erythema on his feet. The cervical glands on both sides were enlarged. Temperature, 104° F. Patient suffered greatly from burning and itching. Desquamation soon started, but it was six weeks before the last evidences of the disorder disappeared.

Metol, or monomethylparamidophenolsulphate, is a synthetic compound which comes to us in the form of a white, crystalline powder. Its use is limited practically to photography, where it is employed in developers as a reducing agent, either alone or in combination with other agents, such as pyrogallic acid and hydrochinon. Its high standing in the esteem of the photographer is due to its rapidity of action. It is the active agent in the majority of ready mixed developers and developing powders sold to amateur photographers to-day.

Previous to the introduction of the snapshot camera and the simplification of the processes used in photography, the physician was seldom called upon to consider the effects produced upon the skin through contact with solutions containing metol. But to-day, when even the children compete with their elders for photographic honors, we are constantly called upon to observe and to treat certain conditions of the skin, usually of the hands, which may be traced readily to metol as the cause.

Many professional photographers, whose hands are constantly bathed in solutions of metol and who suffer no ill effects therefrom, are wont to scoff at the suggestion of poisoning and allege for themselves a personal immunity. They believe that individual susceptibility or idiosyncrasy is primarily responsible. While the professional photographer's exposure to the action of the chemical is immensely greater than the amateur's, we must not lose sight of the fact that the skin of his hands is much tougher and more resistant, and that his hands are almost constantly in water, thereby diluting the metol taken into the skin. Again, some of the worst cases seen by the writer have been in "old hands" who have always considered themselves immune. In order to further disprove this theory of immunity the writer has applied a normal solution of metol to the soft skin of the upper forearms of two professionals who considered themselves immune. Within forty-eight hours both gentlemen complained of burning and itching and exhibited circumscribed erythematous areas at the site of application. In one case the dermatitis was typical and went on to desquamation; the other soon faded and gave no further symptoms. It remains, however, for us to make many tests of this sort before pronouncing our opinion too positively on the subject of im-

The clinical picture shown in this affection differs in no wise from that of an ordinary acute dermatitis following the application of some irritant or vesicant. Redness, swelling, the formation of vesicles, which subsequently rupture and discharge an alkaline serum, scabbing and finally desquamation; these are the objective symptoms. Subjectively we find intense burning and itching; and when the areas are unprotected and the drying scabs open up cracks in the skin, the patient complains of pain

out of all proportion to the area affected.

In appearance the disease is much like ivy poisoning, but is usually limited to the fingers or hands, and shows no inclination to spread by contact or autoinoculation. In the majority of cases the disease is much less severe than ivy poisoning, the areas more circumscribed; in fact, usually found only on the parts coming in contact with the solution, and showing a tendency towards chronicity not seen in ivy poisoning. The writer has seen several cases in which the forearms were involved, and one case in which the face was attacked, but in all of these was able to get a history of contact with the solution of metol either directly or indirectly through the use of towels contaminated by the chemical. The writer has heard, through photographers, of many cases in which the whole body had been involved and "running sores" had broken out; but investigation almost invariably uncovered some other disease either accompanying the metol poisoning or being mistaken for it. Of five cases investigated, two were syphilitic, two psoriatic, and the other a true pustular eczema.

Once attacked, the photographer has learned to give metol a wide berth. Some sufferers become so susceptible to its effect that the mere drying of their hands upon a towel containing it is sufficient to bring on an attack of burning and itching accompanied by redness and swelling. This phenomenon has been observed twice in the writer's experience.

The average sufferer presents himself complaining of severe burning and itching of the fingers, usually the soft skin of the median and distal phalanges. The surface is red and swollen and covered with tiny vesicles, which soon rupture, leaving the areas denuded and very painful. The serous discharge is very profuse, alkaline in reaction, and soon dries into scabs. If there are hangnails or breaks in the cuticle about the nails, these areas will be painful beyond all reason and if not properly treated tend to persist for many weeks. When seemingly healed they will suddenly open, discharge serum and cause no end of annoyance and pain.

In simple cases, unlike ivy poisoning, the disease seemingly skips the stage of vesiculation and discharge; and desquamation, accompanied by intense titching, alone engages our attention. But where the discharge is present and scabs form and no effort is made to properly protect the abraded surface cracks open into the true skin. These fissures often penetrate deeply into the tissues and are the cause of much pain and discomfort. Desquamation occurs in all cases, from tiny flakes to whole patches of skin, and it is during this stage that the itching is

most troublesome.

When the disease covers large areas, such as the backs of the hands and forearms, there is usually a little fever present during the initial stages.

Before taking up the treatment of this affection, just a few words concerning its prevention. Avoid using metol in any form or strength of solution if there exists any hangnail or break in the skin into which the solution may enter. When developing plates or prints in metol solutions use but the tips of the fingers, and rinse well in clean water after

each contact. When the development is completed wash the hands thoroughly in soap and water, and dry them on a clean towel.

Rubber gloves are awkward, expensive, and short lived. Finger cots are very liable to leak at the top, and are almost as awkward as rubber gloves. Solutions of citric or acetic acids, recommended by some as positive preventives, have proved useless in the author's hands. Heavy oils, lanolin, and petrolatum applied to the hands before using the solutions certainly protect but tend to injure the negative or print. The writer has found a saturated solution of paraffin in benzin to be about as satisfactory as anything in the way of a protective application. The fingers are dipped into the solution before developing and the benzin allowed to evaporate, leaving the skin intimately covered with a thin coating of paraffin.

In the instruction books supplied by the manufacturers of photographic plates, films, and papers certain formulæ are recommended containing other agents than metol for those who find metol injurious. Might it not be wiser to caution the amateur before using the chemical that its use is attended with danger to some, to mention the symptoms by which the affection may be recognized, and to sug-

gest a few, simple, preventive measures?

In the treatment of metol poisoning we must bear in mind that while the cause is specific the disease is pathologically identical with other dermatites produced by irritants, and that the treatment must be along the same lines usually adopted in handling such cases. In other words, there exists, as yet, no specific with which to combat the disease. The majority of photographers who have expressed themselves to the writer believe that metol is absorbed directly into the tissues, passes into the circulation, and is eliminated slowly. In this way they account for the chronicity of the affection. The writer prefers to believe that this chronicity, this constant repetition of attacks, often lasting intermittently for months, is rather due to a devitalizing effect, which metol seems to exert upon the tissues with which it comes directly in contact.

Hundreds of remedies have been published in the photographic press; some of them are worthy of consideration. But almost without exception these remedies are useful only in the chronic form of the disease. The sufferer who attempts to relieve an acute attack of metol poisoning with some of these "prescriptions" is liable to complicate matters rather effectually, to say the least. The disease must be treated like any other dermatitis—symptomatically.

Rest and protection of the parts affected are imperative. If the attack is severe a cathartic is indicated. If the patient is seen early in the attack, before the skin is broken, some cooling, soothing, astringent lotion is advised. Lead and opium wash, black wash, pure or diluted one to four, or the following prescription work nicely in relieving the intense burning and itching:

| Acidi carbolici. | gr. xl to lx; | Pulv. calamine. | 5; | Pulv. zmci oxidi. | 3; | Sir. | Glycerin. | 5; | Aquæ calcis. | 5; | Aquæ ros.e. | 9 | cl. Siv. | M. sig.; Apply freely on cloths. | Shake well. |

It is seldom, however, that we are consulted before the skin is broken. When this condition supervenes and the surface is bathed in the watery discharge, care must be taken to protect the parts thoroughly and to use the blandest of applications. The stearate of zinc makes a very agreeable application where a dusting powder is desired. To this may be added one or two per cent. of carbolic acid or salicylic acid. When an ointment is indicated in this stage the following is mild and soothing:

| B | Hydrarg. chlor. mitis,gr. x; | |
|------|------------------------------|--|
| | Acidi carbolici,gr. x to xx; | |
| 7./[| Ung. aquæ rosæ, | |

In the chronic form of the disease, when cracks form and the skin is indurated or scaly, an ointment containing one or more of the stimulating drugs gives the best results:

| 19 | Acidi salicylici,gr. 30; |
|---------------------------|--------------------------|
| | Pulv. amyli, |
| | Zinci oxidi, |
| | Ung. petrolati, |
| M. | |
| or | |
| $\mathbf{P}_{\mathbf{k}}$ | Ichthyolis, |
| | Acidi salicylici,gr. xx; |
| | Acidi borici,gr. 30; |
| | Ung. zinci oxidi, |
| M. | |

To either of these prescriptions resorcin, or oil of cade, gr. xx, may be added, if indicated.

516 NOSTRAND AVENUE.

NEURASTHENIA VENTRICULI AND GASTROPTOSIS.

By Harris Weinstein, M. D., New York,

Visiting Physician to the Philanthropin Hospital, and Gastroenterologist to the German Poliklinik.

Nervous phenomena so often accompany visceroptosis that a great many cases of so called nervous dyspepsia can be traced directly to this cause. Occasionally cases of dislocation of the abdominal viscera are met with in which the nervous manifestations are either slight or entirely absent; they are, however, so infrequent that their bearing on the casual interrelationship between the two conditions is hardly affected. While prolapse of the liver is frequently unaccompanied by serious nervous symptoms, prolapse of the stomach, especially of high degree, is, almost without exception, complicated by more or less severe disturbances of the nervous system. It would be a hopeless task to attempt a description of a typical case, as the manifestations are so protean in character that the experienced clinician is often at a loss to correctly interpret the various nervous phenomena. It is the more difficult to correctly diagnosticate these cases, as most organic gastric diseases sooner or later become complicated by various nervous symptoms. To further complicate matters, the secretory and motor functions of the stomach are almost invariably affected in one or other direction in gastric neuroses, and our best efforts are often baffled by such findings. If in a given case of nervous dyspepsia pain after the ingestion of

food is a prominent symptom, if there is tenderness of the epigastrium, and in addition we find increased acidity of the gastric contents, we may be tempted to diagnosticate ulcer of the stomach. Again, there may be a complete anacidity of the gastric juice, severe epigastric pain after meals, a high degree of anaemia, and emaciation from inantion, loss of appetite, nausea, and vomiting. Such findings would lead us to suspect malignancy. In a great many of these cases submotility is a prominent symptom, and if complicated by secretory disturbances may easily give rise to false deductions. Apart from the stomach we have other organs to contend with, especially the condition of the blood, heart, and kidneys.

It is evident from what has been said that the diagnosis of such a condition is anything but a simple matter. It is not, however, my object to point out the difficulties we have to contend with in order to arrive at a correct diagnosis, but rather to point out the distinctive importance of the various prominent nervous symptoms and their proper interpretation. A careful history may at once suggest a neurosis, but to jump to conclusions from the history is dangerous practice and never leads to a satisfactory diagnosis. Besides, there is the danger of being influenced by our first impressions, and we are apt to be guided by them in the interpretation of physical findings. It is, therefore, best to make a mental note of such impression, and then to proceed to a consideration of the various symptoms and physical signs in an unbiased manner. The most constant and important symptoms are the following: Pain, pressure in the epigastrium, pyrosis, sour eructations, globus hystericus, nausea, vomiting, anorexia, abnormal appetite, a sensation of emptiness referred to the stomach, difficulty of deglutition, indefinite pain in the back, abdominal cramps, constipation, or diarrhœa alternating with constipation, attacks of faintness and of impending dissolution, tachycardia, headache, and dizziness. In addition, there are various manifestations indicative of vasomotor affection. All these symptoms may be present in a given case, or only a few principal symptoms masked by a great number of bizarre and unusual sensations. I shall confine myself to an analysis of those symptoms only which would suggest organic disease of the stomach.

The most constant and perplexing symptom in this neurosis is pain referred to the stomach. The textbooks distinguish between pain due to a neurosis and that due to organic disease of the stomach by its relationship to the ingestion of food. If pain is present while the stomach is empty then it points to a neurosis, and if it appears immediately or some time after a meal then it points to organic disease. While in some cases this is true, it is also certain that in an equally large number of gastric neurosepain comes on only after the ingestion of food. Still a gastric analysis will disclose no cause for such pain, for the secretory function may be perfectly normal. Again, there may be an overacidity or an anacidity of the gastric juice and the motor function undisturbed; either of these conditions cannot be held responsible for the pain, for such secretory anomalies are frequently present without giving rise to painful sensations. In those rare cases of gastroptosis where the prolapse is so extreme as tocause a kinking at the junction of the pylorus with the fixed duodenum, thus giving rise to a relative pyloric stenosis, the pain can be explained as being caused by spasmodic contractions of the hypertrophied gastric musculature in its efforts to propel the food through the narrowed lumen of the pylorus. For the minor degrees of gastroptosis such explanation cannot be advanced, and we must have recourse to a possible hyperæsthesia of the gastric mucosa. To properly interpret this symptom we must rely upon other features of the case, also a careful and exhaustive inquiry into its character and its various manifestations may give us a hint to its proper meaning. While pain due to gastric ulcer is always present after a meal, and, if constant, is aggravated even after the ingestion of liquids, such is not the case in hyperæsthesia. Now and then even a heavy meal can be indulged in without causing the slightest unpleasant sensation in the stomach, but such confession is not willingly made by the neurotic, and it must therefore be obtained from him while thrown off his guard. The pain due to organic disease can pretty nearly always be ascribed to some definite cause and its onset traced back to some definite time by the patient; in a neurosis both the cause and onset of the pain are enveloped in a mist that the patient cannot dispel. Another deciding factor from a distinguishing standpoint is the presence or absence of localized tenderness over a circumscribed area in the epigastric region. While such an area of tenderness is present in ulcer, in neurosis tenderness of the entire region is complained of and is never There can be no difficulty in differcircumscribed. entiating the epigastric tenderness which occurs in gastritis or benign pyloric stenosis, as the stomach contents presents too characteristic a picture to be mistaken for a neurosis.

The method of eliciting a circumscribed painful area is important. A suddenly applied blow with the finger over the epigastrium will call forth resentment on the part of the patient as well as of the abdominal muscles, and pain will be complained of whether it is present or not. It should be performed in an easy and methodical manner by pressing the epigastrium with one finger very lightly at first, constantly and gradually increasing the pressure until pain is complained of. The importance of distinguishing between a mere hyperæsthesia and pain due to organic disease cannot be overestimated as much from a positive as from a negative standpoint. It is just as serious to err on the safe side, because in that case a strict diet will not only weaken and emaciate the patient, but will also aggravate the nervous condition.

In the absence of typical attacks of gallstone colic, cholelithiasis often presents a very obscure condition, difficult to distinguish from ulcer or gastric neurosis. While ulcer may be excluded by the absence of occult blood in the stomach contents and in the fæces, we have no means by which to distinguish it from a neurosis. In my experience I have found the symptoms of obscure gallstone disease more persistent and severer, the pain is colicky in character, there is no epigastric tenderness, and pain may often be elicited on pressure over the gallbladder region. There is often tenderness over the entire hepatic area, and is best elicited by light tapping with the closed fist. While none of these symptoms can be fully relied on for a diagnosis, the entire picture of the disease will be helpful in deciding on the true condition. The sensation of pressure in the epigastrium along with nausea, occasionally accompanied by vomiting immediately or some time after a meal, headache, and dizziness, are frequent accompaniments of chronic gastritis. While examination of the gastric contents will greatly aid in distinguishing between gastritis and a neurosis, the results of such examination are not always easy of interpretation. Mucus may be found in a neurotic condition of the stomach as well as in gastritis, and other elements indicating irritation of the gastric mucosa are not at all infrequent, as in gastroptosis there is frequently a mild catarrhal condition of the mucous membrane, especially when accompanied by depression of the muscular tone of the gastric walls. As for the variability of the secretory function I have already mentioned above. Frequent gastric analyses will, however, by the variability of the results, suggest an explanation for these symptoms.

Heartburn and sour eructations are apt to be present in those periods of a neurosis when the gastric secretion is overacid, but it is by no means always The gastric juice may be of normal or even subnormal acidity, and heartburn may be present. This, I believe, is, as in the case of epigastric pain, due to oversensitiveness of the gastric mucosa. In prolapse of the stomach there is often a sensation as of a foreign body in the throat; it is frequently aggravated after a meal. Whether the dragging of the prolapsed stomach on the œsophagus has a bearing on this abnormal sensation I cannot positively affirm, but from the fact that such sensation is aggravated after a meal this explanation seems

plausible.

In a previous paper I reported a case of extreme gastroptosis with paroxysmal tachycardia of eight months' duration, which was immediately relieved on the application of a well fitting abdominal bandage. I then tried to explain the tachycardia by presuming that the prolapsed stomach dragging on the vagi interfered with their proper functioning. Whether my assumption is correct or not, I have since met with a number of cases of gastroptosis with this complication.

A sensation of emptiness in the stomach and of abnormal hunger is often present in overmotility, but it may also be due to a purely nervous condition. In prolapse of the stomach the colon is also displaced to a greater or lesser degree, and as a result there is constipation. Owing to decomposition of the fæcal matter and formation of noxious substances, a colitis develops sooner or later with a re-

sulting diarrhœa.

I have made no mention of the physical examination of the abdominal viscera advisedly the better to impress its importance. While a hurried physical examination, the history and laboratory cannot be relied on for a positive diagnosis in these cases, a careful examination for anomalies in position of the abdominal organs will often clear up the most obscure condition. It is always well to bear in mind that there is frequently a physical cause for neurasthenia, and that one of the most frequent causes is visceroptosis.

841 LEXINGTON AVENUE.

Our Renders' Discussions.

A SERIES OF PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows: LXXVII.—How do you treat varicose ulcer? Closed

August 15, 1908.)

LXXVIII.—How do you treat acute coryza? (Answers due not later than September 15, 1908.)

LXXIX.—How do you treat sick headache? (Answers

due not later than October 15, 1908.)

Whoever answers one of these questions in the manner most satisfactory to the editors and their advisers will receive a prize of \$25. No importance volutever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested that we have to the traction. (but not required) that the answers be short; if practica-ble, no one answer to contain more than six hundred words.

All persons will be entitled to compete for the prize, whether subscribers or not. This prize will not be awarded whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. The prize of \$25 for the best essay submitted in answer to question LXXVI has been awarded to Dr. Beverley Robinson, of New York, whose article appeared on page

PRIZE QUESTION LXXVI.

THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

(Continued from page 459.)

Dr. Wm. F. Bernart, of Chicago, says:

The subject can be considered under the following classification: 1, General considerations; 2, antirheumatic treatment, (a) by mouth, (b) locally, (c) hypodermically; 3, local use of heat or cold; 4, mechanical; 5, treatment of complications.

General considerations .- I. Environments .- Patient must be placed in well ventilated room, the temperature of which, if possible, should not fall

below 70° F.

2. Rest.—Absolute rest, patient taking position

of greatest comfort.

3. Bowels.—Unless successful cathartic has recently been taken, give immediately one of the following: Calomel, 0.016 gramme (1/4 grain), every half hour until 0.20 to 0.325 gramme (3 to 5 grains) have been taken, or magnesium sulphate, 15 to 30 grammes (1/2 to 1 ounce). After the first free catharsis the bowels are kept open if necessary by the use of cascara sagrada at night time or the use of a saline cathartic in the morning. A severe catharsis is not indicated.

4. Diet.-Give no food until after first catharsis; after this give skimmed, fermented, or buttermilk until the overacute symptoms of the disease have subsided, after which a more varied diet can be added. A full diet is not allowed until patient has fully recovered. Water is given systematically, the patient receiving from four to six ounces

Introducamatic medication.—1. By mouth, minister sodium salicylate well diluted with water or milk until the ringing in the ears is secured. This, in the adult, usually requires the use of 8 to 12 grammes (2 to 3 drachms) during the first twenty-four hours; after this continue with 0.65 to 1 gramme (10 to 15 grains) every two hours. This latter dosage is sufficient to keep patient well under the influence of the drug. If taste alone becomes nauseating the drug can be given in capsules. If the full constitutional effects of the drug are obtained, but the desired influence over the disease is not forthcoming, or if the salicylates positively disagree with the patient, it is advisable to give the alkaline treatment a trial. This consists of the administration of potassium citrate or acetate, sodium carbonate or liquor potassæ; 1.32 grammes (20 grains) of the three former or 1.32 c.c. (20 minims) of the latter are given well diluted every two hours. Alternating the salicylate and the alkali seems to be more effective in some cases; this is especially true in cases partially nontolerant to the salicylates. Salicin in 0.65 gramme (10 grain) doses can be used; this drug is less irritating than the sodium salicylate. The use of 0.65 grammes (10 grains) of aspirin every six hours, this preparation displacing the dose of one of the others being given, is influential in assisting in the control of pain.

2. Locally:

| \mathbf{R} | Guaiacol, |
|--------------|--------------------------------|
| | Oil of wintergreen, |
| M. | |
| or | |
| \mathbf{R} | Gum camphor, |
| | Chloral hydrate,5.00 parts; |
| | Oil of wintergreen,5.00 parts; |
| | Fl. ex. of cannab. indica, |
| | Alcohol,30.00 parts. |
| 3.4 | |

Either one of these mixtures is painted, every twelve hours, over the entire surface surrounding the involved joint; the parts are then covered with a thin film of cotton and oiled silk or sheet rubber. The latter formula is more effective when the pain is superficial and of a neuralgic character.

3. Hypodermically.—This consists of the injection of a solution of sodium salicylate either into the tissues, joints, or veins. Injections into the tissues are painful and can be discarded in favor of the injections into the joints or veins. When a large joint, such as the knee, is involved, from 3 to 5 c.c. of a three per cent. solution of sodium salicylate can be injected direct into the intraarticular space. This frequently will quickly reduce the pain, the effusion being gradually absorbed. A better method, however, is the injection direct into a vein. The solution used is as follows:

| | | | | 8.00 | |
|-------|--------|------------|------|-------|--------|
| | | | | 2.00 | |
| | Water, | distilled, | | 50.00 | parts. |
| 74.77 | , | | | | 1 |

During the first twenty-four hours two to three injections of 2 c.c. each are given; after this a daily injection of 2 c.c. will usually suffice. The veins of the forearm should be used. This method is recommendable because of the promptness of the effects produced; it rapidly reduces the pain and effusion, and this without the disagreeable accompaniments attending the internal salicylate medication; it is especially indicated in all cases nontolerant to the administration of salicylates by mouth, and in all cases where the usual procedures do not The method is not produce the desired results. dangerous.

Local use of heat or cold.—The local use of ice is occasionally of service and should be used when the skin is hypersensitive and when heat seems to be ineffective. The application of heat is either local or general, and either dry or moist. The general application is of advantage when numerous joints are involved or later in the attack to produce diaphoresis.

Treatment of complications.—Fever.—If this is high and persistent and not reduced by the anti-rheumatic treatment, it is advisable to resort to the

use of some antipyretic drug.

Pain.—If severe and persistent use either morphine, cocaine, or heroin hypodermically, prefer-

ably the latter two.

Endocarditis.—By the intravenous injections of the sodium salicylate combined with other indicated treatment.

Hyperidrosis.—If sweating caused by the disease

is exaggerated, use atropine or ergot.

Nephritis.—Give mild diuretics in moderation only. Exclusive milk diet. Produce diaphoresis providing same does not exist.

Dr. W. Emory Hyskell, of Meadville, Pa., states:

A patient with acute articular rheumatism should occupy a large, cheery room of uniform temperature, free from draughts and as far away from all noise and confusion as possible. He should be kept absolutely at rest in bed, not being allowed to sit up or make any muscular exertion whatever, so as to give rest to the heart and to the affected joints. His bed should be narrow and have a smooth, fairly firm, yet elastic mattress. As the patient should never become chilled, he should be placed between light blankets and wear flannel nightgowns which have been opened clear down the front and along the sleeves, so they can be easily removed when they become damp with perspiration.

For the first few days, when the pain in the joints is severe, apply a dressing saturated with Fuller's lotion or with leadwater and laudanum. Prevent all movements of the affected joints, fixing them with well padded splints if necessary. In a few days apply an ointment of equal parts of ichthyol and lanolin, surrounding the joints with cotton batting and a pressure bandage. Massage should be

used in prolonged cases.

As long as there are fever and other acute symptoms milk is the most suitable article of diet. Light broths, soups, buttermilk, oatmeal water, and egg albumen may also be given. Feed the patient in small amounts about every three hours. Lemonade (with but little sugar) and plenty of water should be given to flush out the kidneys and carry off the effete products of destructive metabolism. Keep all the emunctories active. Avoid alcoholic stimulation.

The salicylates still hold first place in the treatment of acute articular rheumatism. Give strontium or sodium salicylate, 20 to 25 grains, every three hours. Sufficient doses must be given to relieve the pain or produce cinchonism; small doses are useless. The dose is then lessened and adapted to the severity of the disease and to the susceptibility of the patient. Potassium bicarbonate or acetate should be given with the salicylates in sufficient doses to render and keep the urine alkaline. Phenyl salicylate, salicin, aspirin, and oil of gaultheria are often useful in difficult cases. If the stomach is

irritable, oil of gaultheria (or methyl salicylate) should be applied directly to the joints on cotton batting and then surrounded with a gutta percha

covering

If the disease proves very obstinate, give sodium iodide and wine of colchicum seed, and apply blisters or the Paquelin cautery above and below the affected joints. Avoid opiates if possible, yet do not allow too much exhaustion from pain and loss of sleep. Warn your patient of the liability to cardiac trouble in this disease and of the increased danger that would be caused by rising too soon, by muscular movements, or by excitement of any kind. Watch for and treat any cardiac complications should they arise.

The patient should be kept in bed, and small doses of the salicylates continued for ten or fifteen days after the temperature has become normal. Tonics of iron, arsenic, quinine, and strychnine

should be given during convalescence. (To be concluded.)

Therapeutical Motes.

The Medicinal Treatment of Trachoma.-Ormond (The Practitioner, August, 1908) considers the application of a weak silver nitrate solution the most satisfactory treatment for the second stage of trachoma where the patient complains of pain and discomfort, hotness and itchiness of the eyes, with the lids swollen and thickened. A solution of silver nitrate, in distilled water of the strength of one or two grains to the ounce, should be used three or four times daily after the conjunctival sac has been thoroughly washed out with one of the following lotions: corrosive sublimate, formaldehyde, or chinosol, of a strength of 1 in 10,000 parts of water. The washing of the eyes should be repeated every two or three hours, according to the amount present. The following procedure is advised: Place the patient in a chair with his head well thrown back, or, better still, lying on a couch or table. Have the lotion ready mixed with warm water in a basin beside you; into this put some pledgets of absorbent cotton. In addition, a large piece of dry absorbent cotton will be needed, which should be held against the patient's cheek to absorb the lotion as it escapes between the eyelids. Press this gently against the cheek with the third and fourth fingers of the hand, leaving the thumb and first finger free to hold the lids apart. Take in the free hand one of the soaked pledgets of cotton, hold it over the inner canthus, allowing the lotion to run from it through the parted lids to the external canthus, from whence it will be absorbed by the dry cotton on the cheek. Continue this flushing of the conjunctival sac for two or three minutes, constantly moving the lids so as to insure that the lotion will reach the upper fornices of the conjunctival sac. It being sometimes more difficult to deal with children, the following hints may be valuable. After thoroughly cleansing the outside of the lids, allow some of the lotion to remain over the inner canthus in a little pool. Then, the child being on its back, when persuaded to open its eyes, some portion of the lotion must of necessity enter the conjunctival sac, and so make it unnecessary for the operator to keep the lids apart

NEW YORK, SATURDAY, SEPTEMBER 12, 1908.

EXPERIMENTAL CAISSON DISEASE.

During the last five years the building of submarine ways has progressed with great rapidity. In New York alone excavations beneath both the East and North Rivers have been extensive and prolonged, and numerous cases of caisson disease have occurred of which we have heard little. An excellent clinical paper by Erdman is almost the only literature that has resulted, notwithstanding the unparalleled opportunities. From the experimental side French and English workers have been more active. Vernon, Boycott, Damant, and Haldane have contributed some very suggestive work, and in a recent communication by Boycott and Damant (Journal of Pathology and Bacteriology, April) the interesting feature of the distribution of extravascular bubbles in the spinal cord is dwelt upon.

It is fairly well conceded that the sudden giving up of the gases held in the blood under pressure is the most dangerous feature of caisson disease. Lesions may take place in almost any organ of the body, but those of the joints and of the nervous system seem to leave the more permanent after effects. The rate at which different animals and different parts of the same animal take up gas on exposure to compressed air is a difficult matter to decide, but in general it is proportional to the volume of the blood relative to that of the tissues and the rate of the circulation. The blood itself is almost instantly saturated and the kidney almost as rapidly, but, on the other hand, other parts of the body do not reach saturation within four or five

hours. Conversely, it is true that, on the release of the pressure, the excess of gas that is taken up will escape from different tissues at rates which will depend upon the activity of the circulation in the various tissues. If this activity is sufficiently great, the excess of gas taken up by the tissues may, on decompression, be removed by the blood and escape by diffusion through the lungs so quickly that actual bubbles may not be formed. Hence more bubbles are formed in those organs in which the circulation is comparatively sluggish. Thus, one rarely finds them in muscles or in glandular structures (kidney, liver, etc.), while synovial structures, bile, amniotic fluid, fat, and the white matter of the spinal cord are more prone to have bubbles formed within them, to the disadvantage of their functions.

The spinal implications in caisson disease have always been among the severest and most striking, and this study on the distribution of bubbles in the cord is unique. The authors show that bubbles are much more frequent in the white than in the gray matter, almost five times as much in the one as in the other; while those that do occur in the gray matter are usually found on the edge, whereas in the white matter the bubbles may be deeply immersed. The bubbles in the anterolateral columns are about twice as abundant as in the posterior columns. So far as topography is concerned, the lumbar enlargement escapes with the fewest bubbles. while the dorsal and upper lumbar portions suffer the most. The richer supply of blood in the cervical enlargement may account for its relatively lessened implication. Bubbles in the medulla oblongata and pons Varolii were not found in the animals under consideration (goats), which is not in accord with what has been observed in human beings. A very definite relation between the occurrence of bubbles and the incidence of necrosis is established in these experiments. This necrosis is due to the blocking of the circulation by intravascular bubbles, and in these areas, therefore, bubbles would be particularly apt to form, as the excess of gas could not be carried off from the tissues by the blood. The necrosis of bony tissues is probably explicable in the light of these findings.

In goats, paraplegia was a striking result of decompression. It was due in all the cases to softening of the spinal cord. The necrosis was confined for the most part to the central portions of the white matter, and the lower dorsal and upper lumbar regions were mostly involved. The distribution is strikingly similar to that found in man. Infarcts are rare, though emboli are seen in large numbers in the lungs and liver, accounting probably for some of the obscure general symptoms and delayed deaths. In the temporary cases of "the bends," evidence of

a few scattered degenerated fibres is obtainable by the Marchi method. In some mild cases in the animals experimented on no permanent damage could be detected. The story is a striking example of the direct application of experimental methods to lesions found in man in a disorder which, if we but knew it, has been not uncommon in New York during the last few years.

A MEDICOLEGAL FARCE.

A story attributed to the Neue freie Presse, of Vienna, is to the following effect: A dead body was found floating in an Austrian river, and its appearance was indicative of an atrocious murder. Popular interest in the case became keen, and an official medical examination of the remains was made with great minuteness, including an investigation of the contents of the stomach. The medical experts, according to the account, were sure that a murder had been committed, and they even went so far as to assert, apparently on the strength of the fact that the food found in the stomach was not such as a human being in his senses would eat, that the victim was insane. But the story was soon spoiled by a gentleman who declared that probably he could explain it. He went on to say that he had recently shot a bear and skinned it, whereupon his servant, disobeying his instructions, had cast the carcass into the river. Then the laugh was on the medical experts, and it resounded all over Austria. There is a possibility, however, that the bear story was a hoax, and, for the sake of our Austrian brethren, we incline to that opinion.

THERAPEUTIC INTRACRANIAL CON-GESTION.

In the Zentralblatt für Chirurgie for July 11th Professor Carl Ritter lauds the application of a band to the neck as a means of preventing vomiting after ether anæsthesia. In over sixty cases in which congestion hyperæmia of the brain was produced by constriction of the vessels of the neck, not a single patient vomited either during or after the operation. The mode of procedure is simple; the ether is given in the usual way, and the operation follows immediately upon the supervention of anæsthesia. Having finished his task, however, the surgeon immediately-before the emergence of the patient from the narcosis-applies a tight band to the neck, so as to obstruct the circulation in the cervical bloodvessels. The band is allowed to remain in place for from half an hour to an hour. The first effect observed as a sequence of the cerebral congestion thus induced is, according to Ritter, the relatively quick emergence of the patient from the anæsthesia; the second, as already intimated, is the suppression of the vomiting so commonly observed, especially when the stomach is overloaded.

These are interesting observations, and, if confirmed elsewhere, may result, perhaps, in some modification of the method of giving ether at present in vogue. While conceding this, however, it is but simple justice to note that the compression of the vessels of the neck in conjunction with the administration of ether, and indeed many other remedies, is no new procedure, in this country at least. Twenty-five years ago and more Dr. J. Leonard Corning published a brief monograph (Carotid Compression, New York, 1882), in which, after an historical résumé of the literature of digital compression of the vessels of the neck, he went on to describe certain instruments designed by himself for compressing the vessels of the neck, notably the carotids, for various periods of time, from minutes and hours, in fact, to days and even weeks. These instruments, ingeniously fitted to their work, were tried by their designer in an extensive series of cases, especially in epilepsy and congestive headache. Finally, in a concluding chapter, Corning said: "I have myself employed carotid compression in conjunction with very moderate doses of the bromides, as well as of hyoscyamus and chloral; and I have seen small doses of these drugs, which by themselves would have remained ineffective, produce most excellent sedative effects when employed in conjunction with carotid compression." Corning explicitly stated in concluding his brochure: "Very recently I have made trial of carotid compression in conjunction with inhalations of nitrous oxide gas, chloroform, and ether."

This seems to be the first account in medical literature of an attempt to enhance and prolong the effects of medicinal agents upon certain parts of the nervous system by retarding or suspending the circulation in the region involved by pressure applied to the bloodvessels. Obviously the interference with the deportation of the medicament is the chief cause of the intensification and prolongation of its effects. It is this principle that Corning subsequently extended and applied to such good purpose in the medication and more particularly the anæsthetization of the peripheral nerves (New York Medical Journal, September 19, 1885). It should not be forgotten that Corning has also sought to achieve a more direct action of various remedies upon the brain by spraying them into the nasal cavity and shortly thereafter compressing the jugular veins by the application over each of a small dry cup, the two cups being joined together in front by an adjustable steel band, and the whole appliance held in place by an elastic strap, which, passing around the neck, is secured behind by a buckle (Medical Record, December 31, 1892). The exhaustion of the cups he achieved in one of two ways. I. By the aid of a small air pump. 2. By placing the subject in a compressed air chamber and connecting the dry cups with the external atmosphere by the aid of small rubber tubing, with an appropriate stopcock in the wall of the chamber was from six to eight pounds above that of the normal atmosphere. (See his work on Pain, pages 265 ct sea.)

Besides these ingenious proposals and devices, Corning also invented appliances for the simultaneous compression of the carotids and faradization of the cervical sympathetics. The first account of these undertakings appeared in this journal nearly twenty-five years ago (New York Medical Journal, February 23, 1884). Neither space nor the specific purposes of this writing, however, permits of their discussion in the present issue. A brief statement of the salient features must suffice.

THE RECENT CHRONOLOGY OF THE ORIENTAL PLAGUE.

A valuable pamphlet entitled The Present Pandemic of Plague, prepared by Assistant Surgeon General J. M. Eager, of the United States Public Health and Marine Hospital Service, traces the progress of the disease in recent years in the form of a chronological record, beginning with the year 1894, when the plague, escaping from an endemic focus in the province of Yunnan, reached the seaport city of Canton. This was the Indo-Chinese variety, or "strain," of the disease, which Dr. Eager thinks has been shown to possess greater power of diffusion than the variety which is endemic in Western Asia. For five years before that there had been annual outbreaks of the plague in localities distant from its endemic centres-places in India, Japan, Arabia, Persia and Russia-but these outbreaks did not lead to a pandemic, if that term can properly be applied to the subsequent widespread prevalence of the disease.

According to a rough estimate, there were 120,-000 deaths from the plague in Canton between March and August, 1894, though there was not a single case in the foreign quarter, with a population of about 300. From Canton the disease spread to Hongkong. In 1895 cases were reported in Hongkong, Amoy, Macao, and Foochoo, but little attention was paid to them. The plague reached Bombay in 1896, probably from southern China, and in the same year it appeared again in Hongkong, where it has ever since been epidemic, and invaded Formosa, in which island also it has continued to prevail. There were a few cases in Japan, Asiatic

Turkey, and Russia. In 1897 there were more than 73,000 cases in India, mostly in the Bombay presidency, though the disease was widely scattered over western and northern India. There was a severe epidemic in Formosa, and there were moderate outbreaks in China, Japan, and Turkey. This was the year of the international conference in Venice, where the preventive measures undertaken by various nations were made uniform.

In 1808 the number of cases in India was more than doubled, and there was an alarming increase in the northeastern and central provinces. In that year the disease reached Calcutta and Madras, also the islands of Madagascar and Mauritius. In 1899 there was a continued increase of the plague in India, though there was a decrease in the Punjab. The disease invaded Egypt, but was confined to Alexandria. It also extended to the French Ivory Coast, the Hawaiian Islands, New Caledonia, Portugal, Russia, Austria, Paraguay, Brazil, and Argentina. In 1900 Cape Colony was attacked, as were also the Philippines and various countries of Australasia. There were a few cases in Scotland, England, Wales, and California (twenty-two fatal cases in San Francisco). In 1901 there was a great increase in India, notably in Bombay. Cases appeared also in the Straits Settlements, in Siam, in European Turkey, in Italy, in Great Britain, and in California.

In 1902 there was a still further increase in India, especially in the presidency of Bombay and in the Punjab, and the disease visited Mexico. There were small outbreaks in the countries that had previously been invaded. In 1903 there was an alarming increase in India, amounting to 1,127,000 cases, with 835,000 deaths. Algeria, British South Africa, Chile, and Peru were the additional scenes of the plague. In 1904 the disease caused more than a million deaths in India. In 1905 there was a slight abatement in India, but the prevalence was fearful in the Punjab. In 1906 there was a great decrease in India, but in 1907 there was another great augmentation; in all India there were about 1,400,000 cases, with 1,200,000 deaths. In that year there were seventy-six deaths in San Francisco and three in Seattle. The narrative, gloomy in the extreme in the case of India, has its warnings for the whole civilized world.

THE SPINAL TREATMENT OF TETANUS WITH MAGNESIUM SULPHATE.

Dr. Griffon and Dr. Lian, who report a case of the successful treatment of tetanus with spinal injections of magnesium sulphate, have summarized our present experience with that plan of treatment (Bulletins et mémoires de la Société médicale des hôpitaux de Paris, July 30th). They find that nine cases have been recorded, with three deaths. As

two of the cases were of the fulminant variety, they think we might say that there had been but one death in seven cases that admitted of a reasonable degree of hope. They are inclined to think it expedient to reduce the amount of the drug employed. The American surgeons, they remark, used a cubic centimetre (about a quarter of a drachm) of a twenty-five per cent. solution for each twenty-five pounds of the patient's weight, but they have produced like results with no more than half that amount. They would begin with the smaller quantity, and increase it if necessary. Atropine sulphate is to be injected in case the respiration becomes embarrassed.

A CORRECTION.

In Dr. Wright's article on The Treatment of Tuberculosis by the Administration of Mercury, which appeared in our issue for August 29th, charts 13 and 14 were accidentally transposed. The legends remaining the same, the cuts themselves should have been shifted.

Obituary.

HENRY FARNUM HOLT, M. D., of Philadelphia

Dr. Holt, who was born in Greenfield, N. H., in 1831, died at his home, in Philadelphia, on Saturday, August 20th, aged seventy-seven years. He was graduated in the class of 1857 from Harvard University, and from the Medical Department of the University of Pennsylvania in the class of 1859. During the civil war he was a surgeon in the Federal army. In 1891 he was surgeon to Peary's Arctic expedition. He was a member of the faculty of the Central High School for forty-one years, first teaching anatomy, physiology, and hygiene, and afterward biology. Dr. Holt was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Rews Items.

Changes of Address.—Dr. George F. Dalton, late house surgeon to the Manhattan Eye and Ear Hospital, New York, has moved to 6 Maple Street, Springfield, Mass.

The New Home for Incurables in Hamilton, Canada. —This institution, erected on the grounds of the House of Refuge, at a cost of \$35,000, was formally opened, with suitable ceremonies, on the afternoon of Wednesday, August 26th.

The Buffalo Medical Clinic.-The first regular menthly meeting of this organization for the year was held on the evening of Thursday, September 3d, Dr. James Stoddart presiding. The chief feature of the programme was a paper on Pain by Dr. Fred Hoffman.

The Gloucester County, N. J., Medical Society will hold its eleventh annual social session at the Woodbury Country Club, Woodbury, N. J., on Thursday, September 17th, from 6 to 11 o'clock. Dr. George Evans Reading, 179 South Broad Street, Woodbury, N. J., is the secretary of this society.

The Third International Conference of the Carers for the Insane.—Dr. Smith Ely Jelliffe, of New York, and Dr. William A. White, of Washington, have been appointed by the Department of State as delegates to represent the United States at this conference, which is to be held in Vienna, October 7 to 11, 1908.

The Medical Society of the County of Richmond, N. Y.—The regular monthly meeting of this society was held at the Staten Island Academy of Medicine on Wednesday, September oth. The paper of the evening was read by Dr. Boleslaw Lapowski, of Manhattan, on Further Progress in the Conception and Management of Syphilis.

The Floating Hospital of St. John's Guild made its last trip for this season on Saturday, September 5th. The guild's Seaside Hospital, at New Dorp, Staten Island, will remain open until the end of the month. It is still crowded to its utmost capacity. Over two thousand mothers and children have been cared for at this hospital during the

Franklin Maternity Hospital, Philadelphia.-This hospital, which is a charitable institution, was opened to receive patients on September 3d. Dr. Edward T. Rosenthal is the physician in charge. The following were elected officers of the hospital: Dr. A. H. Dunn, president; Dr. Edward Rosenthal, vice president; Dr. Joseph Langbord, treasurer; and Mr. J. Simpkins, secretary.

Contagious Diseases in Chicago .- During the week ending August 29, 1908, there were reported to the Department of Health 246 cases of communicable diseases, as follows: Diphtheria, 86 cases; scarlet fever, 37 cases; typholofever, 47 cases; tuberculosis, 41 cases; pneumonia, 5 cases; whooping cough, 13 cases; measles, 12 cases; chickenpox, 2 cases; diseases of minor importance a cases. 2 cases; diseases of minor importance, 3 cases

Physicians' Fees in France.—During the last ten years the number of practising physicians in France has been nearly doubled. There are now nearly 20,000 physicians in the republic, and about 2,000 are graduated from the medical schools each year. As a result of this competi-tion doctors fees are very small in France, in some districts one franc being all that is paid for a doctors call.

Richmond, Va., Academy of Medicine and Surgery. Richmond, Va., Academy of Medicine and Surgery.—
The regular meeting of this organization was held on
Tuesday, September 8th. Dr. George Ben Johnston read
a paper entitled Diagnosis and Treatment of Chronic Pancreatitis, and Dr. G. Paul La Roque read a paper entitled
Differential Diagnosis of Intraabdominal Tumors. The
general discussion which followed was opened by Dr. M.
Pierce Rucker.

Improvements in the Memphis, Tenn., City Hospital. The work of improving the equipment of this hospital has been going steadily on for some months past, and the institution is now one of the most up to date and best equipped in the country. An x ray machine has been purchased, a model sterilizing plant has been installed, and arrangements are being made for the establishing of a bacteriological laboratory in connection with the hospital.

To Prevent the Spread of Tuberculosis in Tennessee.

—A conference was held in Nashville recently in the office of the City Board of Health, for the purpose of devising means to prevent the spread of tuberculosis. Members of the State and county boards of health, the county and city boards of education, the antituberculous league, and any other citizens particularly interested in the problem were invited to attend the meeting and offer suggestions. invited to attend the meeting and offer suggestions.

The Medical Society of the Borough of the Bronx.—
A stated meeting of this society was held on Wednesday, September 9th. Dr. Henry Roth presented reports of cases of sarcoma of the thyreoid, hypernephroma of the right kidney, and carcinoma of the sigmoid. Dr. William H. Kahrs read a paper on the Diagnosis and Treatment of the Toxemias of Pregnancy. Dr. S. S. Graber read a paper on the Diagnostic Significance of Uterine Harmorthage

Scientific Society Meetings in Philadelphia for the Week Ending September 19, 1908:

Monday, September 14th, -Wills Hospital Ophthalmic

Nonday, September 15th.—Dermatological Society; North Branch, Philadelphia County Medical Society.
Wednesday, September 16th.—Association of Clinical Assistants, Wills Hospital; Franklin Institute, Friday, September 18th.—American Philosophical Society.

A Union Meeting of Medical Societies .- A number of medical societies from Vermont, New Hampshire, and Massachusetts will meet at Northfield, Mass., on Tuesday, Natissachusetts will meet at Northneid, Mass., on Tuesday, September 22d. An excellent programme has been prepared, which includes papers by Dr. George G. Sears, Dr. Harry H. Germain, Dr. Herman F. Vickery, Dr. Joel E. Goldthwaite, Dr. John Jenks Thomas, and Dr. Timothy Leary. A general invitation is extended to all members of the medical profession to be present and take part in the discussions. discussions

A New Building for the New York Dispensary.— Plans have been filed for a new building for this institu-tion, to be erected at 145 and 147 Worth Street, to replace the old building on Centre Street which it has occupied for more than a quarter of a century. The new building will be a one story and basement structure, in the style of an Italian renaissance palace, with a large central doorway, and will be lighted by a dome ceiling of paneled glass. will contain a diet kitchen, a drug store, a dentist's office. small isolation wards, and a tuberculosis ward. The estimated cost is \$25,000.

The Rhode Island Medical Society.-The quarterly meeting of this society was held in Providence on Thursday afternoon, September 3d, Dr. F. B. Fuller, of Pawtucket, president of the society, in the chair. A paper entitled Insanity in the Light of History was read by Dr. Fred B. Jewett, and discussed by Dr. Willard H. Greene and Dr. William McDonald, Jr. Tuberculin in Diagnosis was the title of a paper read by Dr. Frederick T. Lord, of Roston. Among those who participated in the discussion Boston. Among those who participated in the discussion of this paper were Dr. Jay Perkins, Dr. Harry L. Barnes, and Dr. Helen C. Putnam.

The National Medical Association.-This association, The National Medical Association.—This association, which is composed of colored physicians, held its tenth annual convention in New York recently, and elected officers for the ensuing year as follows: President, Dr. P. A. Johnson, of New York; vice president, Dr. W. S. Lofton, of Washington, D. C.; general secretary, Dr. J. A. Kenney, of Tuskegee Institute, Alabama; treasurer, Dr. A. Wilberforce Williams, of Chicago; chairman of the Section in Medicine, Dr. C. W. Childs, of Washington, D. C.; chairman of the Section in Surgery, Dr. A. M. Curtis, of Washington, D. C. The association will meet next year in Boston.

Charitable Bequests .- By the will of Mr. Frederick Cooper Hewitt, who died recently in Owego, N. Y., the New York Postgraduate Medical School and Hospital re-New York Postgraduate Medical School and Hospital receives \$2,000,000; Yale University, \$500,000; the Little Missionary Day Nursery, New York, \$200,000; the Free School for Crippled Children, New York, \$100,000; the Netherwood, N. J., Fresh Air Home, \$100,000; American Society for the Prevention of Cruelty to Animals, New York, \$10,000; the Sheltering Arms Society, New York, \$10,000; the Sheltering Arms Society Temperance Industrial and Collegiate Institute, Claremont, Va., \$3,000, and the Coburn Free Library, Owego, N. Y. \$3,000. A few days before his death Mr. Hewitt gave \$22,322 to the R. A. Packer Hospital, Sayre, Pa.

The Medical Association of the Southwest, whose membership is limited to the members of the State associations of Missouri, Arkansas, Texas, Kansas, and Oklaclations of Missouri, Arkansas, Texas, Kansas, and Oklahoma, will hold its third annual meeting in Kansas City, Mo., on October 19, 20, and 21, 1908. The officers of the association are: President, Dr. Thomas E. Holland, of Hot Springs, Ark.; secretary, Dr. F. H. Clark, of El Reno, Okla.; chairman of the Section in Surgery, Dr. Bacon Sanders, of Fort Worth, Tex.; chairman of the Section in Eye and Ear Diseases, Dr. F. Haynes Buxton, of Oklahoma Medicine, Dr. F. Young, of Springdale, Ark.; chairman of the Committee on Arrangements, Dr. John Punton, 532 Altman Building, Kansas City, Mo.

A Joint Meeting of Medical Societies in Frederick, A Joint Meeting of Medical Societies in Frederick, Md.—The medical societies of Frederick and Washington Counties, Md., met in joint session in Frederick recently. The attendance was good, and at the close of the meeting a banquet was served in the Hotel Braddock. The programme included the following papers: A Message to Western Maryland, by Dr. B. W. Goldshoro, president of the Medical and Chirurgical Faculty, Baltimore: State Care of the Insane, by Dr. A. P. Herring, secretary of the Maryland State Lunacy Commission: Prevention of Typhoid Fever, by Dr. C. W. G. Rohrer; When is Rheumatism Not

Rheumatism? by Dr. C. W. R. Crum, of Brunswick; Parasteen by Dr. C. W. R. Crum, of Brunswick; Parasites, by Dr. E. Tracey Bishop, of Smithsburg; Medicine in the Tropics, by Dr. A. T. Poole, of Burkittsville; The Clinical Use of Medical Remedies of Unknown Composition, by Dr. C. R. Miller, of Mason and Dixon; Noblesse Oblige, by Dr. V. M. Reichard, of Fairplay; Sunset in Greece, by Dr. S. S. Davis, of Boonsboro.

The Mortality of New York During the Month of August.-During the month of August, 1908, the total number of deaths was 5,971, which was 1,345 less than in August of last year. The principal causes of death were: Typhoid fever, 73 deaths; measles, 24 deaths; scarlet fever, 23 deaths; whooping cough, 26 deaths; diphtheria, 63 deaths; cancer, 282 deaths; meningitis, 51 deaths; heart diseases, 503 deaths; tuberculosis, 641 deaths; alcoholism, 38 deaths; pneumonia, 381 deaths; diarrhœa, under two years of age, 1,339 deaths; appendicitis, 41 deaths; Bright's disease, 170. There were 461 violent deaths, of which 25 were from sunstroke, 76 from drowning, 29 from railroad accidents, 21 from horses and vehicles, 16 from homicide, 64 from suicide.

The Mortality of Chicago.—According to the Bulletin of the Chicago School of Sanitary Instruction for the week ending August 29, 1908, there were reported to the Department of Health of the City of Chicago during the week 584 deaths from all causes, as compared with 575 for the previous week, and 616 for the corresponding period in 1907. The annual death rate in 1,000 of population was 14.09, as against 15.24 for the corresponding week last year. The principal causes of death were as follows: Apoplexy, 10; Bright's disease, 31; bronchitis, 8; consumption, 65; cancer, 33; convulsions, 1; diphtheria, 9; heart diseases, 47; intestinal diseases, acute, 173; nervous diseases, 16; pneumonia, 25; scarlet fever, 5; suicide, 13; typhoid fever, 9; violence (other than suicide), 35; whooping cough, 1; all other causes, 103.

Infectious Diseases in New York:

We are indebted to the Bureau of Records of the Department of Health for the following statement of new cases and deaths reported for the two weeks ending September 5. 1008:

| | —-Au | g. 20 | -Se | pt. 5—— |

Personal.-Sir William Ramsay has had conferred upon him the honorary degree of doctor of medicine by the University of Jena, on the occasion of the elebration of the three hundred and fiftieth anniversary of the found-

of the three housests.

Ing of the university.

Dr. Henry M. Hurd, medical superintendent of Johns
Hopkins Hospital, has been appointed a member of the Maryland State Lunacy Commission.
Dr. S. Weir Mitchell, of Philadelphia, has been elected a

or, L. P. Barclay, at one time a representative of the Bausch & Lomb Optical Company, Rochester, N. Y., died 1 September 1st. Professor E. Kraepelin, of Munich, has been in this

country for the past month, visiting in the West.

Vital Statistics of New York .- During the week ending August 20, 1908, the total number of deaths reported to the Department of Health was 1,284, as compared with 1,385 for the previous week, and 1,472 for the corresponding period in 1007. The annual death rate in 1,000 of population was 15.15, as against 17,02 for the corresponding week last year. Of the total number of deaths 672 were in Manhattan, 100 in the Bronx, 402 in Brooklyn, 75 in Queens, and 35 in Richmond. The death rate in Brooklyn was the lowest for the five boroughs, being 14.05, while that in Richmond was the highest, being 23.81. In Manhattan the death rate was 15.29; in the Bronx, 15.93, and in Queens, 16.82. Of the total number of deaths 5.43 were of children under five years of age, and of these 278 were due to diarrhead diseases. There were 2.650 births, 4.33 marriages, and 132 still births reported during the week.

The Health of Minneapolis .- During the month of July, 1908, the following cases of transmissible diseases were reported to the Department of Health: Diphtheria, 30 cases, 5 deaths; scarlet fever, 14 cases, o deaths; smallpox, 4 cases, o deaths; typhoid fever, 5 cases, 2 deaths; tuberculosis, 26 cases, 22 deaths. The following deaths were reported from other transmissible diseases: Tuberculosis, other than that of the lungs, 8 deaths; diarrhœa and enteritis, under two years of age, to deaths; two years and over, 3 deaths. There were 9 suicides. The total number over, 3 deaths. There were 9 stitledes. The total number of deaths from all causes was 229, in an estimated population of 300,000, corresponding to an annual death rate in 1,000 of population of 7,02. Of the total number of deaths 54 were of children under five years of age. There were 17 still births, II males and 6 females.

A Decrease in New York's Infant Mortality.—The Report of the Conference for the Summer Care of Babies, recently submitted by Dr. Walter Bensel, chairman of the conference, shows the most encouraging results in the methods employed this year in the work of caring for infants during the summer months. In the thirteen weeks since the work was begun there were 2,868 deaths of children under one year of age and 3,404 under five years of age, as compared with 3,020 and 3,704, respectively, in 1907. The of inspectors, twenty. All told, 26,075 mothers were interviewed and instructed in their homes; 8,747 revisits were made; 4,926 instructions were given to mothers on piers; 318 lectures were given in ninety-two schools; 1,188 instructions were given to mothers attending 318 school lectures, for which an attendance of 10,878 is recorded; sick babies received 1,372 visits at their homes; 1,071 treatments were given sick babies on piers, while 361 treatments were given to sick babies brought to school lectures.

The New Corps of Women Nurses for the Navy.—

The New Corps of Women Nurses for the Navy.-The first examination for women nurses for the naval hospitals will be held in Washington on Saturday, September 12th, at the Naval Medical School. Twenty positions will be filled from the list of eligibles resulting from this examination. amination. Other examinations will be held later until a corps of a hundred or more capable nurses has been obtained. In addition to the provision to be made for the hospitals at Canacao and Yokohama, the hospital at San Juan will require women nurses. The tour of duty at these foreign ports will be two years. As the corps increases in numbers, it is proposed to form a reserve corps, consisting of nurses who have received an honorable discharge, and who obligate themselves to return to active duty when an emergency requires it. The pay of nurses in the new corps has been fixed as follows: \$40 a month when on duty in the United States, and \$50 a month when serving on hostial ships or honorable the continuated limits of the United pital ships or beyond the continental limits of the United States. Quarters and subsistence will be provided in ad-A nurse when assigned to duty as chief nurse at a hospital, where not less than two nor more than four nurses are stationed, will receive an additional \$5 a month; where not less than five nor more than nine nurses are stationed, \$10 a month, and where ten or more nurses are stationed, \$25 a month, Wiss Esther V. Hassan, of Baltimore, has been appointed chief of the corps at a salary of \$1,500 eyear. Miss Hassan served on the hospital ship Relief during the Spanish War, and on the Isthmus of Panama in IQOI

Bith of Current Miterature.

2. A Study of One Hundred and Thirty-six Cases of Diarrhœa Occurring on the Boston Floating Hospital during the Summer of 1907 .-Lucas reports 136 cases of diarrhoea, of which eighty-four were infectious diarrhœa and sixty-three were intestinal indigestion. The majority of these cases, on admission to the hospital, had the typical movements of intestinal infection; small, watery green, or yellow, consisting mainly of mucus, frequently with curds. Of all these cases, only twentyfour had blood in their movements while on board, so that of eighty-four cases of the infectious type only twenty-two, or twenty-six per cent., had bloody movements. Initial high temperature was a noticeable feature in these severe cases only by its absence, low or subnormal temperature being more often the rule. Vomiting was a factor of enough moment in 119 cases to require careful attention. There were several distinct types with which the author became perfectly familiar before the season was over: (1) The utterly hopeless cases with severe toxæmia, presenting the picture of "coma vigil," with eyes half open, lustreless, and with a proneness to develop corneal ulcers. (2) The toxic type with or without frequent stools, and very often the infants in this class had no movements without irrigations or only one to three a day, yet they were certainly toxic. It was often noted that the toxicity lessened with the frequency of the stools, thus showing that the number of movements is not always a good criterion from which to judge the severity of the disease. (3) Children between one and two years, active, and in perpetual motion, until completely overwhelmed with toxines, were very trying to treat. (4) The patients with frequent stools that did not appear very sick or toxic, but often dragged on to become numbered with the obstinate chronic cases. The initial cleanser in most cases was castor oil in liberal amounts; one and one half to three drachms for children under one year. Calomel was given only when oil could not be tolerated, and in these cases it was rarely retained. That high irrigations are of value there can be no question, but that too much weight is attached to frequent colon irrigations, the author is convinced. Of far greater value, where there is pronounced vomiting, is the practice of lavage. Of the 119 vomiters, forty-six had repeated stomach washings, frequently three or four times a day. A half hour before feeding was attempted, the stomach was given a thorough washing. Lucas concludes that the best of our present methods of treatment of these cases is starvation, carefully watched, followed by any one of the weak mixtures, low in fat. The guide to starting milk in any form is the general picture the child presents rather than the temperature or any

one symptom. Saline infusions are one of the most valuable aids in carrying out the starvation treatment and supplying the liquid quotient. The benefit of colon irrigation is overestimated, though useful in moderation; once in twenty-four hours being sufficient. The lavage is a very important factor when the infection has reached or attacked the stomach. Stimulation is of little value in extreme cases.

4. Erythema Multiforme with Visceral Lesions.—Hall reports two such cases. It is to be noted that of the fourteen leading phenomena mentioned as occurring in Osler's group of twenty-nine cases, the number present in any given case varied between four and ten. Purpura was noted in twenty-two cases, urticaria in seventeen cases, œdema in five cases, erythema in fourteen cases, fever in fourteen cases, colic in twenty-five cases, vomiting in . fifteen cases, diarrhœa in five cases, hæmorrhages in fourteen cases, nephritis in fourteen cases, albuminuria in fifteen cases, arthralgic pains in seventeen cases, endocarditis in three cases, and enlarged spleen in three cases. Various other manifestations were noted in one or two cases only. In the first case there were ædema, erythema, fever, colic, vomiting, hæmorrhages (from the kidneys), nephritis (including the albuminuria, classified separately in Osler's article), arthralgic pains, and enlarged spleen; in the second case, purpura, cedema, erythema, fever, hæmorrhage, arthralgic pains, and the group of symptoms relating to the nervous system, coma, hyperæsthesia, photophobia, etc. The first case is like many of those heretofore reported, while the second varies in detail from any on record, but the general picture conforms to the type.

- Artificial Respiration.—These papers were read before the Section in Surgery and Anatomy of the American Medical Association at the fifty-ninth annual session. Schäfer, of Edinburgh, remarked that in cases of drowning the prone pressure method of artificial respiration is always indicated. Its advantages are: 1, That it is fully efficient; 2, that

it can be performed without fatigue by a single individual; 3, that it is simple and easily learned; 4, that it allows the tongue to fall forward and the mucus and water to escape from the mouth, so that the tendency of these to block the passage of air, which is inherent to the supine position, is altogether obviated. It can be applied equally well in attempting to revive a patient whose respiration has ceased in consequence of an overdose of chloroform or other anæsthetic. One of the difficulties and dangers of a general anæsthetic is the excessive secretion of saliva and mucus. This, with the subject in the prone position, would tend to flow out of the mouth. With chloroform another source of danger is the tendency of the heart to undergo fatal inhibition, owing to the influence of the drug on the vagus centre. Both these dangers are obviated by the hypodermic administration, prior to the operation, of a small dose (1/50 grain) of atropine sulphate. Circumstances may arise in surgery in which artificial respiration is called for, but which would not permit of the employment of either of these methods. In these cases the simplest apparatus which can be employed is an ordinary bellows or a piston cylinder. It is not even necessary to introduce the air directly into the trachea, for, as Horvath observed, if the nozzle of a bellows is introduced into one nostril, the other nostril being left open but the mouth kept shut, it is possible by a vigorous movement of the bellows to distend the lungs quite efficiently, and by repeating the movement regularly, to carry on artificial respiration. But in surgical operations which involve the opening of both sides of the chest it would be safer to perform intubation of the larynx, or even temporary tracheotomy. In any case, it is highly desirable in such circumstances to adopt, if possible, the prone position for the patient. Under some circumstances a tendency to dyspnœa is increased by the supine position.—Robinson said that the results of thirty operations under positive pressure with seventy per cent. recoveries were encouraging. Thirty operations and twenty-five experiments proved that emphysema and circulatory changes did not occur with a properly regulated apparatus. In the use of positive pressure the escape of deoxygenated air must be amply provided for.—Sauerbruch described his method. He based his work on the known principles of the difference between the intrabronchial pressure and the pressure at the surface of the pleura, about 7 to 8 mm. Hg, which served to keep the lungs distended. If the normal relationship between these pressures was disturbed, as by opening the thorax, the lungs collapsed, and the result was a pneumothorax, which might be followed by serious disturbances, such as dyspnœa, displacement of the diaphragm and heart, vagus reflexes, etc. Believing that these complications would not occur if the normal relationship of these pressures could be maintained, he was led to carry out the following experiments: The ends of a glass cylinder were sealed with gutta percha paper. One end was perforated by three openings, two small ones and one large one; the opp site end was perforated by a single large opening. The animal was placed in the exlinder, so that the head proteuded from one of the

large openings, and the legs and lower part of the body through the other opening. He passed his hands in through the small openings, endeavoring to keep the cylinder airtight. Next, the cylinder was exhausted sufficiently to reduce the air pressure 10 mm. Hg; then he opened the thorax-and the lungs did not collapse, nor was the respiration disturbed in any way. This primitive apparatus was replaced by a better and a larger one, and then by a small operating room, in which he performed a number of intrathoracic operations, such as resection of the lung and œsophagus and operations on the heart, and always with the same result, total absence of pneumothorax. The result of these experiments was the building of an operating room for practical use. The first operation done in it (resection of œsophagus) proved positively that the results obtained in animal experimentation could be duplicated in the case of the human being-that pneumothorax could be prevented. Having estabfished the correctness of the principle of his method, it became necessary to elaborate the operative technique. Definite rules had been laid down for certain operations. So far as the anæsthetic was concerned, it was remarkable how small a quantity was necessary to produce complete anæsthesia, and then only at the time of opening and closing the thoracic cavity. During the remaining steps of the operation very little of the anæsthetic was required. It had been shown that it was unwise to reduce the pressure more than 3 to 5 mm. Hg. Before concluding the operation it was essential to raise the pressure to 7 or 8 mm. Hg, so that the lungs might become fully expanded, filling the chest cavity completely. The strictest asepsis must be observed, as in abdominal operations, and complete hæmostasis was of the greatest importance, especially when entering the thoracic cavity, so that as little blood as possible would enter. The author described the indications and his technique.

7. Serum Diagnosis of Syphilis .- Butler observes that the serum reaction for syphilis is specific. It is found positive in from ninety to ninetyfive per cent. of all cases with syphilitic manifestations, positive in fifty to sixty per cent. of latent cases, positive in from seventy to eighty per cent. of parasyphilitic diseases. The reaction is in many cases influenced by treatment of the patient, and it is not improbable that this number would be greatly increased if the reaction were pursued throughout prolonged treatment. A positive reaction indicates activity of the specific virus, and is an indication for antisyphilitic treatment. While a positive reaction indicates syphilis, a negative reaction does not have an equal negative value. It is diagnostic of a systemic infection, whether acquired or inherited, and not an organ diagnostic measure. The reaction will be found of enormous advantage in distinctive diagnosis in every department of medi-

8. The Nature and Cause of Œdema.-Fischer calls attention to the fact that dead bodies kept in water become cedematous. This is due to the fact that after death the tissues become acid, and absorb water from their surrounding medium. For the

same reason gangrenous tissues swell if a source of water is furnished them either from without or through the blood and lymph vessels. In gangrene due to occlusion of a vein it is well known that the tissues are ordinarily moist and swollen, while a gangrene due to occlusion of an artery is ordinarily dry. The conception of ædema offered here holds for local as well as generalized cedemas. In fact, one form of local ædema furnishes what amounts to experimental proof of the ideas advanced. Reference is made to the rapidly developing cedema which follows the stings or bites of various animals capable of carrying formic or other acids into the wound produced by them. Formic acid is exceedingly active in increasing the affinity of various colloids for water. This explains why its introduction into the tissues—as through a flea bite—is followed by such a rapidly developing local ædema. That circulatory disturbances are not primarily responsible in this case is indicated very clearly by the fact that the cedematous tissues are initially white, and only after resolution has commenced does an increased flow of blood occur through them. Flea bites can, in fact, be perfectly mimicked with a needle, a little formic acid, and a hydrophilic colloid. If a gelatin plate is pricked with a needle dipped into formic acid, and a little water poured over the gelatin plate, wheals soon develop on the surface of the gelatin, which, in shape and in the rate of development are identical with those which follow the bite of a flea or the prick of a formic acid laden needle in the skin of a human being. As another form of local cedema which finds a ready explanation on the basis of the ideas advanced here, are glaucoma and the imbibition of water by the crystalline lens.

The Influence of Overweight and Underweight on Vitality.-Symonds gives a table of average weights for men, compiled by the Association of Life Insurance Medical Directors. It can be noted that each added inch in height calls for an addition of 3 per cent. in the weight. This rule will apply, if liberally interpreted, to all but the small man. The weight increases steadily with the age in each horizontal line up to the year forty-five among the little men, the year fifty among the middle sized men, and the year fifty-five and even sixty among the tall men. One is almost tempted to say that the taller the man the longer it takes him to reach full maturity as shown by his weight. In the very tall this rule does not seem to apply.

The largest number of individuals was found at five feet eight inches of height, and this is true for all ages below sixty. The age period showing the largest number of individuals was the decade twenty-five to thirty-four, and this is true for all heights. In the case of women our standard is not yet assured. Dr. Shepherd analyzed the records of 3,016 female applicants accepted for insurance. This number is too small to give accurate results. In general, the record shows that at the age of twenty women are lighter than men by six to nine pounds. This difference gradually diminishes with advancing age. By the time the menopause is reached it becomes one or two pounds only, and after this is may be obliterated. A patient is not considered overweight unless it is more than 20 per cent. above the standard weight for the height and age. For example, at age forty the standard weight of a man five feet six inches tall is 150 pounds. We would not regard him as an overweight until he had passed 180 pounds, which is 20 per cent. in excess of his standard weight. As long as the weight is not below 80 per cent. of the standard-i. e., not more than 20 per cent. below the standard—a patient is not considered of underweight. The differences between overweights and underweights are stated by the author: The mortality among all those, irrespective of age, who are between 20 and 30 per cent. below the standard weight, is 96 per cent., while the mortality of all, irrespective of age, who are between 20 and 30 per cent. above the standard, is 113 per cent. These figures alone would show that overweight is a much more serious condition than underweight. On the other hand, we must take into account the fact that until recent times overweights were accepted more freely by insurance companies than underweights. To put it in another way, underweights were selected with more rigid care than overweights. The old idea that an overweight had a reserve fund to draw upon in case there was a run on his bodily bank was prevalent, although it was recognized that excessive fat might be harmful and should exclude the risk, on the ground, perhaps, that it was a form of capital which was not active. Similarly, an underweight was considered to be undercapitalized, and if his bodily bank had to go through a panic like pneumonia, or hard times like organic heart disease, he would become insolvent and bankrupt. As a result of this method of thought, our underweight mortality is rather better and our overweight mortality rather worse than if both sets had been accepted under exactly the same conditions. But, even if we make full allowance for the difference in selection, he is convinced that the same percentage of overweight is a more serious matter than if it were underweight. The excessive weight, whether it be fat or muscle, is not a storehouse of reserve strength, but it is a burden which has to be nourished if muscle, and which markedly interferes with nutrition and function if fat. This does not apply to the young, those below twenty-five years of age. Here a moderate degree of overweight is much more favorable than underweight. In fact, up to age twenty-five an overweight not to exceed 110 per cent. of the standard is upon the whole good for the individual. It seems to indicate a certain hypernutrition and robustness of physique which is favorable to the subsequent life. Underweight among these young people, on the other hand, is unfavorable, and in some cases indicates commencing disease or the tendency thereto. But when we pass the age of thirty these conditions are reversed, and the difference between overweight and underweight in their influence upon vitality becomes more marked with each year of age. Of course, for the best interests of health, one should be near standard weight, and that is the sermon which we should preach to our patients.

2. Spinal Analgesia.—Barker reports a third series of one hundred cases of spinal analgesia. The conditions produced by spinal analgesia appear to be, as regards the actual performance of the operation, more favorable for the surgeon and not more disagreeable for the patient than those produced by general anæsthesia. Deaths will unfortunately continue to occur after grave operations under any and every form of anæsthesia. Beginners should not use the method in extremely debilitated patients or severe operations on the abdomen requiring high analgesia. The best results are obtained in operations below the umbilicus, and best of all on the pelvic organs. The head and shoulders should be kept well raised at all times throughout the operation and after, and all shifting or jerking of the patient should be interdicted. A minute on the side after injection seems long enough, and then the patient should be gently rolled over on the back without any sudden movement or lifting of the pelvis. The need

of care in the exact measurement and preparation of the drug cannot be too much insisted on.

5. Antral Disease.—Tilley discusses disease of the antrum in relation to general and special surgery. The general surgeon sees cases of alveolar abscess, dental cysts, malignant disease of the antrum, and necrosis of the upper jaw. Acute and chronic inflammation of the antrum is of special interest to the rhinologist and dental surgeon. Infection of the antrum may arise by way of the nasal cavities or through disease of certain teeth. Acute antral suppuration by the intranasal route is usually due to infection by the organisms of the acute specific diseases. Of these influenza is the commonest, though bad cases follow typhoid and scarlet fever. Many cases recover spontaneously, and failure to do so is usually due to hindrance to free drainage by coincident pathological conditions within the nose. A second common cause of antral suppuration is infection from a diseased tooth, an apical abscess, or suppurative periodontitis. Traumatism is a less frequent cause. Chronic suppuration within the antrum is usually the sequela of an acute attack of inflammation which has failed to undergo resolution. Such failure may be due to the virulence of the initial inflammation, to defective drainage caused by pathological intranasal conditions, or to the continuance of the initial cause of the inflammation—for example, an apical dental abscess which continues to supply infective material to the inside of the antrum. A debilitated state of the patient's general health will be a strong predisposing factor in the formation and continuance of chronic suppuration in one or more of the sinuses. The pus obtained from some cases of antral suppuration may contain organisms similar to those occurring in the mouth. Occasionally bacilli distinctive of dental caries may be isolated from the pus of an antral abscess. In cases of chronic suppuration streptococci are found in eighty per cent., as compared with sixty per cent. in more recent cases. In recent cases virulent organisms are met with twice as often as in cases of chronic suppuration. Clinical evidence supports the view that the antrum is more frequently infected by way of the nasal cavity, and this is corroborated by bacteriological investigation. When the inflammation is the result of dental infection, the offending tooth should be removed and free communication with the antrum made through the alveolus. The sinus should then be gently irrigated with a mild antiseptic solution. The opening should be kept open by means of a plug, and the irrigations performed at intervals. When antral suppuration is of nasal origin, the prognosis is less favorable. The primary constitutional disease must be suitably treated, and the local discomfort caused by the complicating acute sinusitis allayed. Locally, efforts must be chiefly directed to promoting the free and spontaneous discharge of pus from the antrum by way of the natural ostium, by: (a) Directing the patient to lie in bed with the diseased antrum uppermost; (b) the application of cocaine and adrenalin solutions to the regions around the middle meatus, this may be done every four or six hours; (c) scarification of these regions; and (d) inhalation of mentholized steam. If these means fail the antrum should be punctured through its inner wall in the inferior meatus, and irrigated.

I. Granular Kidney .- Warrington states that the cardinal symptoms on which a diagnosis of granular kidney is made are: (1) Cardiovascular changes; (2) ophthalmoscopic examination; (3) manifestations of chronic or acute renal toxamia; and (4) the urine. The cardiovascular changes come first in importance. In some cases the most pronounced changes fall on the vascular system, general arteriosclerosis being present, and the kidney substance being comparatively slightly affected by fibrosis. In other cases the kidney is profoundly fibrotic and greatly reduced in size and weight. The causes of arteriosclerosis are those of granular kidney-the working of products of defective metabolism, of which the two best known are gout and lead. In granular kidney the thickening of the arteries can almost invariably be recognized. High arterial tension is a normal feature of granular kidney, and when it falls, unless this is brought about by therapeusis, it indicates a condition of failure of compensation. Enlargement of the heart is usually present, and in young subjects can be readily made out, the clinical indications being displacement of the apex beat downwards and outwards, and a well localized and forcible apex beat. In older subjects the hypertrophy is not infrequently masked by the emphysema so often present in the subjects of granular kidney. Auscultation at the apex shows the first sound to be muffled and of low pitch, while the second aortic sound has a characteristic, clear, high pitched, ringing tone. Headache in granular kidnev is often a symptom of chronic toxæmia, but it may be due to the high blood pressure and the disease of the arteries. As regards the urine, the granular, "compensated" kidney behaves like that of a healthy person. A large amount of urine is excreted, and hence the specific gravity is low. Albumin is often absent altogether. Casts, though scanty in number, are nearly always present. At any stage of the disease an acute nephritis may be added to the old standing disease and may be thought to be the primary mischief. A diagnosis of uræmic asthma until the other causes of dyspnæa have been excluded; among these may be mentioned pleural effusion, bronchitis, ædema of the lungs and of the glottis. dilatation of the heart, pericarditis, and hydrops pericardii. The ophthalmoscope often confirms the diagnosis of granular kidney in obscure cases. Only

the arterial changes are absolutely distinctive of renal disease, however. The most characteristic feature is the appearance of small, glistening, woolywhitish patches often arranged in a striate fashion around the macular region. These are degenerative in nature, and are permanent. Hæmorrhages and papillitis occur, but may disappear. From the standpoint of treatment the cases may be grouped as follows: (1) The compensated kidney, where the excretion of urinary products is not greatly interfered with. Here the treatment should be chiefly prophylactic, alcohol, condiments, and strong broths and meat extracts being forbidden. (2) The acute exacerbations, where the treatment resembles that of acute nephritis. (3) The cases with cardiac failure; here the freshly made infusion of digitalis combined with some vasodilator is of special value. (4) The more chronic symptoms of renal toxæmia. (5) The hopeless cases, where the desires and tastes of the patient should be met as far as possible. For toxæmic symptoms hot rectal saline injections at a temperature of 110° F. are of great value. Morphine should not be withheld in these cases; it is invaluable for restless, painful nights with cardiac dyspnœa. It is very doubtful whether the excretion of sodium chloride has anything to do with the production of uræmia or œdema.

3. Prehistoric Syphilis.—Smith has investigated the alleged discovery of syphilis in prehistoric Egyptians by Lortet and Fouquet, based on the presence of "ulcers" on the cranial and long bones. writer holds, however, that there can be no doubt whatever that the injuries described as the result of syphilis were really produced long after death and burial and that the damage was done by small bee-

4. Cerebrospinal Meningitis.-Watt gives a short account of the symptomatology, diagnosis, and treatment of a series of eighty-six cases of epidemic cerebrospinal meningitis. The condition most frequently present was rigidity of the posterior cervical muscles. Vomiting and headache were very constant features, but muscular pains were only present in about one quarter of the cases. Kernig's sign was present in over three quarters of the cases. As regards the rash, an herpetic eruption was present in fourteen cases, a petechial eruption in sixteen cases, and an erythematous in twenty-one cases. Direct examination of the fluid drawn off by lumbar puncture showed meningococci in twenty-six out of seventy-five cases, but cultures showed the specific organism in seventy per cent. of the cases.

6. Generalized Fætal Œdema.-King reports two cases of generalized cedema of the feetus, and reviews the literature of the subject. Such ædematous children are usually born of women of about the ages of from thirty to thirty-five years who have previously had abortions or premature still births. The mother's health is rarely good, but there is no specific disease associated with the condition. Fœtal anasarca may occur in single or twin pregnancies, and may be associated with hydramnios. The labor is usually premature, but the large size of the child often causes obstruction during labor, and the friability of the tissues when present renders artificial aid difficult. While the maternal prognosis is good the children are either stillborn or live only a few hours. Subsequent pregnancies may end either normally or with premature still births, or, in a few cases, with more cedematous children. The causation is very obscure, especially in those cases where no definite mechanical circulatory obstruction exists. Post mortem examination of one of the writer's cases showed marked disorganization of the suprarenal bodies, and it is possible that the cedema can be attributed to the action of certain unneutralized products of metabolism upon the fœtal capillary endothelium.

LA PRESSE MEDICALE

The Soluble Ferments,
Consideration of Hysteria by the Société de Neurologie
de Paris. Concerning Suggestion,
By Henry Meige.

By R. ROMME. The Reactions of Anaphylaxia,

1. The Soluble Ferments.-Roger prefers to retain the term soluble ferments to denote the colloid products of cellular activity which are diffused among the elements which gave them birth and from which they can be separated by a more or less complex procedure if not in a state of purity at least in a condition which permits their study. Other synonymous terms which have been applied to these substances are diastase, enzyme, and zymase.

2. Suggestion.-Meige reports that the discussion revealed a divergence of opinions dependent largely on the interpretation of the word suggestion; some were accustomed to give it an evil signification, others were not. The definition of the word hysteria also evoked a considerable variance of opinion, and the general impression that resulted was that the term hysteria should be employed with extreme care.

July 20, 1908.

I. Acute and Subacute Tuberculosis. Concerning a Subacute Form of Tuberculous Septicæmia with Pulmonary, Pleural, Cutaneous, Periosteal, Articular, and Periarticular, Endocardiac and Pericardiac Foci, By L. LANDOUZY and L. LAEDERICH.

2. Practical Value of Percutaneous Tuberculinization by

By E. Moro. Means of Tuberculin Ointment.

1. Subacute Tuberculous Septicæmia.--Landouzy and Laederich report the case of a boy, sixteen years of age, who suffered from a subacute tubercular septicæmia with lesions in the parts indicated in the title of the paper. The skin lesion was a multiform erythema nodosum, the periosteal consisted of nodosities of the skull and of the elbow. The cardiac conditions are well shown in the accompanying illustrations.

Tuberculinazation by Inunction.—Moro notes the difference between the results obtained by this method and those of von Pirquet's method. In children presenting no clinical evidences of tuberculosis the percentage of positive reactions obtained by inunction is, on the whole, less than those obtained by von Pirquet's method. The absolute harmlessness of this method presents a great advantage over the

opthalmoreaction.

August 1, 1908.

- General Principles of the Blood Pressure and of Its Variations in the Normal Condition, By G. Weiss.
 Internal Secretions and Psychoses, By LAIGNEL-LAVASTINE.
- 1. General Principles of the Blood Pressure. -Weiss divides the oscillations of blood pressure

into three varieties: 1. Those which are periodical and produced by the pulsation of the heart; 2, those which are equally periodical, are due to respiratory movements, and spread into oscillations of the first class; 3, those which are irregular, without fixed rhythm, and spread into oscillations of the second class.

Internal Secretions and Psychoses .- Laignal-Lavastine says that the frequent coincidence of psychic troubles in glandular syndromata is a fact. Sometimes glandular trouble supervening in infancy or adolescence acts upon the development of the brain, and produces psychic troubles from anomalies of structure. Sometimes glandular trouble comparible with the existence of a relative functional capacity of the organism produces correlative modifications of varying intensity in both the organic and psychic life. Sometimes very extensive glandular trouble produces serious results in the way of intense cerebral reactions which through toxic psychoses bring about a type of mental con-The existence of glandular troubles in psychic syndromata has not as yet received the attention it deserves. Yet the presence of these troubles in certain cases cannot be denied.

I. Pure Mitral Stenosis and Nanism, By Marcel Labbe.
2. Viscosity of the Biood and Iodine, By P. Boveri.
3. Measles and the Red Light, By Florea Simionescu.

r. Mitral Stenosis and Nanism.—Labbe says we have endeavored to refer nanism (the condition of being dwarfed) to syphilis and tuberculosis without reference to the influence of the heart, and to say that infection has caused dwarfed cardiac and vascular conditions, dwarfed teeth, malformations of the palate, and dwarfishness of the body. In order to affirm that in certain cases the nanism is the result of the cardiac lesion and not that of a general dystrophic malady this nanism of cardiac origin ought to possess characteristics which would distinguish it from nanism of syphilitic origin, but this has not yet been demonstrated.

2. Viscosity of the Blood and Iodine.—Boveri says that in his opinion one of the causes of the happy effects of iodine in diseases of the cardiovascular system is the fact that iodine diminishes

the viscosity of the blood.

3. Measles and Red Light.—Simionescu asserts that probably the active agent of measles and its toxine lose their pathogenic properties rapidly under the influence of red light. The red light works differently from a serum and has a strong abortive action. The patient presents a simple feverish state that quickly disappears. Even one of the most dreaded complications, bronchopneumonia, is both benefited and cured by this treatment. The reason given is that the bronchopulmonary complication is due to the measles eruption appearing on the tissue and parenchyma of the lungs. Future observation is necessary to give us the solutions of the mechanism of phototherapy.

LA SEMAINE MEDICALE. August 5, 1908.

. Internal Secretions and Psychoses,

By LAIGNAL-LAVASTINE.

2. Clinical Forms and Diagnosis of Neuralgias,
By Verger.

classifies facial neuralgias thus: 1. The neuralgic pain is continuous with or without paroxysms, and when paroxysms are present they have less intensity and frequency than in the other types. 2. The pain is spontaneous and submits quite readily to the modifying influence of functional excitation or of efforts to move the face and jaws. 3. The pain roused by pressure upon the painful zone, when such a zone exists, is generally slight, with the exception of the neuralgia symptomatic of sinusitis, where one often observes cutaneous hyperæsthesia. It is rarely localized with the precision of the points of Valleix, but is rather a painful zone than points of pain. In the group of chronic neuralgias there is a certain number of cases which have been confounded with tic douloureux. These are obstinate to therapeutical treatment, as is also epileptic neuralgia with which they must never be confounded. Their principal characteristics are: 1, The existence of a continuous pain between neuralgic paroxysms situated in a more limited zone than the territory of the distribution of the corresponding nerve. 2. The likelihood of causing paroxysms by talking and eating. 3. The constant pain produced by pressure upon the painful zone. 4. The frequent existence of pain upon pressure on the points of Valleix. 5. The temporary cure of the pain and paroxysms by the injection of cocaine in the locus Facial neuralgias of radiculoganglionic origin are of two sorts: I. Symptomatic neuralgias from inflamed or neoplastic lesions of the Gasserian ganglion, or of the sensitive root of the trigeminus. 2. Neuralgias corresponding to the clinical type of epileptiform neuralgia, whose character is not yet well known, but it is certain that their organic cause must be sought for beyond the extremities and even beyond the nerve trunks themselves. Verger goes on further to speak at length on neuralgia due to syphilis, tabes, tic douloureux, thoracic neural-gias of peripheral origin, thoracic neuralgias of radiculoganglionic origin, and neuralgias of the lower end of the upper limbs. His article deserves careful reading in the original.

ZENTRALBLATT FUR INNERE MEDIZIN. August 1, 1908.

The Antifermentative Reaction of the Blood,
By Wiens.

I., Antifermentative Reaction of the Blood.—Wiens concludes that every debilitating disease, such as cancer and tuberculosis, leads to an increase of the antiferment content of the blood and to an increase of the inhibitory power of the serum. As this phenomena occurs in every tissue wasting disease, its occurrence is not specific, and it has no particular diagnostic value. If an improvement takes place in the course of the disease, the antiferment content diminishes, the changes being much more marked in the acute infectious diseases than in the chronic ones. These changes seem to bear a definite relation, in the acute infectious diseases, to the opsonic index.

ZENTRALBLATT FUR CHIRURGIE. August 1, 1908.

I. The Treatment of Septic and Pyæmic General Infections, By P. Sick.

r. Treatment of Sepsis.—Sick highly recommends the use of iodipin as a remedy in general sep-

tic conditions. There is a rapid fall of temperature followed by a rapid improvement in the general condition. These results have been noted especially in cases of puerperal sepsis and phlegmonous inflammations, anthrax, and postoperative pneumonia. Sick does not regard the drug as a specific agent, but thinks it is a valuable adjuvant in the treatment of the septic forms of disease.

Proceedings of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of Wednesday, February 26, 1908. The President, Dr. A. M. Eaton, in the Chair.

Hour Glass Contraction of the Stomach.—Dr. JOHN J. GILBRIDE exhibited a specimen which had been removed from the cadaver of a male. contraction had followed the healing of an ulcer. The stomach was divided into two pouches. greater curvature was drawn upward toward the lesser curvature and the opening of communication between the pouches would admit of the introduction of two fingers. The stomach was firmly bound down by adhesions to the posterior abdominal wall on the left side. It was stated, said Dr. Gilbride, that in some instances the viscera might be constricted in two or more places, thus forming two, three, or four pouches. The most common form met with was that in which the stomach was divided into two pouches. Movnihan and others had recorded examples in which the lesser curvature was drawn downward, while the greater curvature was normal in outline.

Ether Anæsthesia.—Dr. Collin Foulkrod believed that the teaching of ether anæsthesia should begin in the second or third year of student life, when groups of two or three men should be trained at the head of the operating table. Ether alone had best stood the test, and it should be given drop by drop on gauze in an insistent manner. The most important factor in preventing shock he believed to be the abolition of fear on the part of the patient. Ether anæsthesia could be made a gradual falling to sleep, and barely enough for the operation should be given. The best guides as to the depth were the breathing and the sensitive pupillary reflex. If the jaw was held forward, shock was eliminated, less ether was required, and the patient was less tired. The abuse of ether and mixed anæsthetics, because of lack of careful, experienced men, he regarded as one of the greatest stigmata upon present day sur-

The Anatomy of the Accessory Sinuses of the Nose, with Special Reference to their Suppuration. Dr. Ross Hall Skillers exhibited a series of lantern slides, the majority of which were photographs of the anatomical preparations of Professor E. Zuckerkandl, now in the Anatomical Institute in Vienna. Dr. Skillern reviewed briefly the anatomy of the lateral wall of the nose in relation to the sinuses. This was followed by the diagnosis between empyema of the sinuses of the first series. The anatomy and suppuration of the sinuses of the second series were then taken up. The demonstration ended with the exhibition of the more common forms of anomalies met with in this region.

Congenital Absence of the Ulna .- Dr. FRANCIS

D. Patterson presented this paper, with the exhibition of the patient and a review of the literature.

The Frequent Necessity of Multiple and Consecutive Operations for Renal Calculi.-Dr. W. WAYNE BABCOCK reported seven cases, indicating the feasibility of operating upon both kidneys at the same time or of doing repeated operations upon the same kidney.' Upon one of the patients bilateral nephrotomy had been done for calculous disease; a year later bilateral nephrolithotomy; at a later time drainage and nephrectomy; finally, from the remaining kidney five stones had been removed. Two years later the patient was active and fairly vigorous. The second patient had six consecutive operations for recurrent calculous disease and pyelonephrosis, and after bilateral nephrostomy, and wore catheters in the kidneys for a year and a half. Finally, the patient came under the author's care. One kidney was removed, the opposite ureter catheterized, and the nephrostomy drainage abolished. Following this the urine cleared and the patient gained over twenty pounds in weight. In all, twenty-five operations were done upon the seven patients for the symptoms produced by stone, with one death. The author concluded that, in the absence of infection, bilateral consecutive operations upon the kidneys were well borne. Nephrolithotomy, especially when done in the presence of pyelitis, for large and crumbly or for multiple calculi, was frequently followed by the renewed formation of stone in the kidney. Nephrotomy gave better late results than pyelotomy. Nephrostomy might not only fail to cure or prevent pyelonephrosis or recurrent nephrolithiasis, but might even favor these conditions. In operating for simple calculous disease of the kidneys, drainage through the loin should, if feasible, be avoided or used only temporarily and with the most rigid aseptic precautions. In bilateral or consecutive operations upon the kidney, spinal anæsthesia by tropacocaine or stovaine was to be preferred.

Meeting of Wednesday, March 25, 1908.
The President, Dr. A. M. EATON, in the Chair.
PSYCHOTHERAPEUTICS.

Psychotherapeutics: its Methods, Scope, and Limitations.—Dr. CHARLES K. MILLS briefly discussed this subject. The story of psychotherapy, he said, was an old one, but was being retold by new raconteurs, with a few additions of value and with many trimmings and adornments. The terms psychic medicine and mystic medicine were not absolutely interchangeable. In a certain sense mystic medicine—the medicine of the savages, of the oracles, of Mrs. Eddy, of the shrine of whatever sorthad in it the psychic element. It appealed to the superstition or the imagination of the individual, playing upon either his normal or his abnormal suggestibility. The psychic medicine in which the doctor should be continuously interested was one in which the use of mental influence for the relief or cure of disease was resorted to on the same scientific principles as was the use of water, medicine, electricity, the surgeon's knife, or the forceps of the obstetrician.

The accepted psychotherapeutic methods of today were considered under the heads of (1) the use of hypnotic procedures, (2) the appeal to suggestibility in the waking state, and (3) the resort to educational or persuasive measures. Dr. Mills was decidedly of the opinion that suggestion in patients in the state of profound hypnosis should not be resorted to, except in a very few extreme cases of hysteria, in which it should be used on the principle that, of two evils we should choose the lesser. The use of suggestion in the waking state was commended, with some qualifications, however, as, like suggestion under hypnosis, it occasionally might result in harm. The suggester, however serviceable he might be to his suffering patient, did not always effect a permanent cure. The truth was not as Du-Bois expressed it, that one was cured as soon as he believed he was cured, but that he was cured when the conditions which had caused and which tended to reproduce his sickness had been removed. In this era of the exploitation of psychic medicine, the community, and even the profession, had been carried beyond the confines of reason. With regard to the admixture of religion and medicine for the purposes of healing, it should be said that in medicine, as in religion, faith was often essential. Harm was done, not alone to the community and to the medical profession, by the psychotherapeutic efforts of enthusiastic but misled clergymen, but eventually to religion itself. Every neurologist of any considerable experience had had pass through his hands many cases of uncured disease in individuals of deep religious sentiments, who had called in their extremity upon Christian Science or some similar healing cult, and, failing to receive the benefit for which they had been led to hope, had lost their faith, not only in the efficacy of the cult to heal, but also in its efficiency in matters purely spiritual. The strongest and wisest opponents of faith cures and divine healing and all similar therapeutic methods or organizations were those who, misled by great promises consciously or unconsciously made, had come back to be cared for and treated by those who only professed for themselves the powers which were given to them by scientific study and by experience with disease.

The Use of the Mental Element in the Treatment of Disease.—Dr. CHARLES W. BURR referred to the value of the personal element in therapeutics, and divided psychotherapeutics into education, encouragement, waking suggestion, suggestion under the hypnotic state, and those occult and mystical and so called religious means of cure. He separated encouragement from suggestion, because in encouragement there was simply a logical talk with the patient, showing him his error in what he thought about himself, showing him that in very truth his condition pointed toward a cure. In waking suggestion the attempt was made to act upon the patient's "unconscious mind," causing him to create in his own mind, without knowing that the physician had caused it, a feeling of well being in the future.

In nervous conditions suggestion was regarded as one of the most valuable agents, but it also was capable of great harm. The case was cited of a patient who was doing well, but who had been receiving suggestions from her nurse toward diseases rather than toward health. Concerning hypnotism in general, it was said that there was no subject in science in which it was more difficult to attain the truth than in this study. Much had been written upon it by people who had not the slightest idea of how to weigh evidence. That the student was en-

tirely at the mercy, not only of the integrity but of the intelligence of the emlpoyer of hypnotism was another difficulty in the study of the subject.

Regarding the occult means of treatment, Dr. Burr believed that there was rapidly growing up in this country a superstition intellectually as gross as had ever appeared in the world's history. The reason for this superstition was too deep a subject for present solution. While the basis of the occult means of treatment was suggestion, they differed from the suggestion used by the physician in that they alleged some power outside the physician himself as being the thing that did the work, and in this in a measure approached the witchcraft of olden times. One evil of the practice of occult means was that persons who could be cured by physical means, if treated promptly, were rendered incapable of cure by the delay. As to the religious element in therapeutics, Dr. Burr believed it would be a very dangerous practice for a religious body to attempt the cure of sick people without constant medical advice.

An Analysis of Psychotherapeutics.—Dr. F. X. DERCUM considered the methods of psychotherapy under the following heads: General methods, including mental rest, mental exercise, and mental gymnastics; special methods, including normal suggestion, direct and indirect; hypnotism and suggestion under hypnotism; and the psychoanalytic method of Breuer and Freud. The advantages of the legitimate use of the general methods and of normal suggestion were dwelt upon and commended. Treatment by hypnotic methods was discountenanced on the ground that hypnotism was simply the artificial induction of an hysterical state, and that the affection from which the patient already suffered was thus compounded with hysteria. The fallacies upon which the psychoanalytic method was based were pointed out, as were also its objectionable features. Freud's theory of the origin of the obsessions through passionate acts of sexual aggression during childhood was considered and its absurdities were dwelt upon. The writer further pointed out that all the functional nervous derangements were characterized by a more or less marked impairment of the general health, that they were more or less the expression of asthenic states, and that improvement in the nervous symptoms ensued upon an improvement of the general health. He also pointed out the advantage of the employment of the general psychotherapeutic measures, such as were embodied in rest, isolation, restraint, etc., while efforts to improve the general health were being carried out.

Book Motices.

III'e publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are I bely to be interested.]

Movable Kidney. Its Pathology, Symptoms, and Treatment. By Harold W. Wilson, M.B., B.S., Lond., F.R.C.S., England, Demonstrator of Anatomy and Chief Assistant in the Surgical Out Patient Department, St. Bartholomew's Hospital, etc., and C. M. Hinds Howell, M.A., M.B., B.Ch. Oxon, M.R.C.P., Lond., Junior Demonstrator of Physiology, Late Casualty Physician, St. Bartholomew's Hospital, etc., With Illustrations. London: Edward Ainold, 1008. Pp. 104.

The authors invite attention to the history of this condition, apparently described first by Mesue, of Venice, in 1561, next by Franciscus Pedemontanus in 1581, then in 1682 by Riolan, who pointed out the important part played in the production of the condition by the rapid diminution of the perinephric fat. In 1839 Pierre Rayer gave a full account of the condition and its symptomatology, and his was followed by Laudan's important work. In 1881 Hahn recorded two successful cases of lumbar fixation of the kidney, naming the operation nephrorrhaphy.

The authors believe that the frequency with which movable kidney occurs has been exaggerated, because the statistics have included kidneys that were palpable, and this was possible in sixty per cent. of the women in the surgical and gynæcological wards at St. Bartholomew's Hospital, although in none of them could abnormal renal mobility be said to exist. The chief characteristics of movable kidney are: I. Increased respiratory excursion. 2. Change of position (accompanied by mobility), including under this heading, a, prolapse, b, rotation of one or other pole, and, c, a combination of a

and b.

The anatomical points are described that are important to maintain the kidneys in proper position; and because the renal fossæ are wider and shallower in women than in men, because women suffer more from chronic constipation, and because of tight lacing, the condition is more frequently found in that sex. The kidney may become movable as a result of the rapid absorption of the capsula adiposa with consequent renal prolapse. Or mobility may be increased, with anterior and inward displacement, either (a) by bulging of the perinephric fascia, or (b) by loosening or stretching of the perinephric attachments to the vertebral column. Or, in traumatic cases, mobility is caused by rupture of the true suspensory ligament of the kidney. The pathological changes in the organ due to either clinical or experimental mobility are described; and the physical examination and symptoms, the diagnosis, and the treatment are reviewed. The authors urge that it is not only desirable but necessary to restrict operations to carefully selected cases, a dictum advanced by Treves and an advisable change from the furor secandi of some operators. The four classes of cases in which nephrorrhaphy is advised have been considered with care, and in each the operation is justified. There is a good description of the method of operation. The text is well illustrated, and the monograph is a valuable addition to the literature of this important condition.

Essentials of Dietetics in Health and Disease. A Textbook for Nurses and a Practical Dietary Guide for the Housefor Nurses and a Practical Dietary Guide for the House-hold. By Amy ELIZABETH POPE, author, with Anna Caroline Maxwell, of Practical Nursing, and Instructor in Practical Nursing and in Dietetics in the Presbyterian Hospital School of Nursing, etc., and Mary L. Carpenter, Director of Domestic Science of the Public Schools, Saratoga Springs, N. Y. New York and London: G. P. Putnam's Sons, 1908. Pp. x-249.

The really practical part of this book seems to us excellent, including the lists of articles allowed and of those prohibited in various morbid states, also the portion devoted to cookery. There is perhaps rather too much of the didactic, but it is fairly well done. The following passage (page 69) strikes us as a delicious piece of generalizing: "In all animals the parts that have had the most exercise in life, e. g., the neck, the legs, especially the lower part, and around the tail, are the toughest, but have the most nutriment and are the most juicy." A most commendable hint is given in this statement (page 25): "In health a food is not necessarily indigestible because it requires three or three and a half hours for digestion." We are glad to learn that onions are "good blood purifiers," and that letthat onions are "good blood purifiers," and that let-tuce, endive, escarole, chickory, and romaine are "cooling," but we regret that eels are omitted from the list of fishes.

Our authors might have been more careful in the matter of diction. On page 141 we are told that "rickets are due," etc. This reminds us of the professional funny man's question "Have you had the measles, and if so how many?" We were not aware that the title of the S. R. Smith Infirmary had been changed to "Smith's Infirmary" (see the title page).

Textbook of Physiological Chemistry in Thirty Lectures, By Emil Abderhalden, o. Professor für Physiologie des physiologischen Instituts der tierärztlichen Hochschule, Berlin, und Universitäts-Professor. Translated by William T. Hall, Instructor in Chemistry, Massachusetts Institute of Technology, and George Defren. First Edition, First Thousand. New York: John Wiley & Sons, 1908. Pp. xiii-722.

Diseases of the Spinal Cord. By R. T. Williamson, M. D. (Lond.), F. R. C. P., Assistant Physician, Royal Infirmary, and Lecturer in Medicine, Victoria University, Manchester. With One Hundred and Eighty-three Illustrations and Seven Plates. London: Henry Frowde and Hodder & Stoughton (Oxford University Press), 1908. Pp. xi-432.

Glandular Enlargement and Other Diseases of the Lymphatic System. By Arthur Edmunds, M. B., M. S., B. Sc. (Lond.), F. R. C. S. (Eng.), Surgeon to the Great Northern Central Hospital, etc. London: Henry Frowde and Hodder & Stoughton (Oxford University Press), 1908.

and Hodder & Stoughton (Oxford University Press), 1908. Pp. vii-230.

Miscellany.

Postgraduate Medical Classes .- It would appear that the Glasgow Royal Infirmary has exceptional facilities for clinical teaching. The indoor daily residence averages 600 patients, and during the year 1907 over 9,000 indoor cases were treated, while more than 50,000 were dealt with in the outdoor and special departments. Including all the attendances, the enormous number of 187,000 came in view during the year. With this large amount of clinical material, the staff have exceptional facilities for demonstrating disease in all its aspects, and it is thought that when the new hospital buildings are completed, the facilities for practical teaching will be unsurpassed by any institution in the United Kingdom. During the last four years carefully arranged postgraduate classes have been conducted, and that they have been fully appreciated and taken advantage of by the profession is shown by the very satisfactory attendances. The classes have not been made up solely of practitioners in the city and neighborhood of Glasgow, but many have traveled long distances in order to benefit by the teaching.

NEW REMEDIES

In order to satisfy a demand for information regarding the additions to our materia medica, the following notes on new remedies have been compiled from the various journals of medicine and pharmacy published in this country and in Europe. Modern chemical synthesis is constantly adding to the number of extrapharmacopeial remedies, and the sources of information regarding them are not readily accessible to practising physicians, being scattered through a mass of literature and entailing considerable research. It is intended to publish these notes regularly, and in this way keep the medical profession informed regarding remedies of recent introduction.

Iodomenine is an iodoalbumin compound with bismuth, which is said to part readily with its iodine and to remain unaltered in the presence of acid liquids. It is, however, quickly decomposed by alkalies in dilute solution, to form the corresponding alkali iodide and bismuth albumin. It is intended as a substitute for the alkali iodides ordinarily prescribed, and is put up in tablets containing the equivalent of the iodine contained in one grain of potassium iodide, the dose being one to three tablets three times daily.

Menstrual Blood, the antiseptic properties of which have long been known, has recently been recommended as an application for the treatment of chancroid (Petersburger medizinische Wochenschrift, 1907, No. 19, through Pharmazeutische Zentralhalle).

Arterenol Hydrochloride has been introduced to take the place of the various preparations of the suprarenal gland, having, it is asserted, the same therapeutic action as adrenalin and analogous compounds, with considerably less toxic action, which makes it possible to give it in larger doses. It is the hydrochloride of aminoethanol pyrocatechin, and forms small, white, odorless crystals, readily soluble in water, but sparingly so in alcohol. It is marketed in the dry form as well as in that of a one in one thousand solution. The aqueous solution produces a slight anæsthetic effect when placed upon the tongue.

Homorenon Hydrochloride is an analogous compound with arterenol hydrochloride, and is chemically defined as ethylaminoacetpyrocatechin hydrochloride. It forms a white powder readily soluble in water and is intended to be given in five per cent. solution in place of the usual one in one thousand solution of adrenalin hydrochloride.

Quinine Anhydromethylene-Citro-Disalicylate is a compound of quinine and novaspirine which contains more salicylic acid and less quinine than quinine salicylate and quinine acetylsalicylate. There are two chemical combinations of quinine and novaspirine which form white, bitter powders insoluble in water, but easily soluble in alcohol. One is an

acid salt containing thirty-six per cent, of salicylic acid and forty-two per cent. of quinine, while the other, which is made from neutral quinine sulphate, and has the same therapeutical properties as the other, contains a lesser quantity of salicylic acid and a correspondingly higher amount of quinine, the proportions being twenty-five per cent. and fifty-nine per cent. respectively. The quinine salicylate ordinarily employed contains thirty per cent. of salicylic acid and seventy per cent. of quinine, while quinine acetylsalicylate is composed of twenty-seven per cent. of the acid and sixty-four per cent. of the base.

Morphosan is a name that has been recently adopted for morphine methylbromate, a morphine substitute of less toxic and habit forming properties than the natural alkaloid. It is not very soluble in cold water, but dissolves readily in hot water. In five per cent. solution it is given in doses of twenty drops by the mouth. Hypodermically it is administered in doses of one twelfth to one sixth of a grain several times daily.

Allosan has been introduced as a potent succedaneum for sandalwood oil, and is stated to be a solid, crystalline, almost tasteless ester of allophanic acid with santalol. It is understood to have the same therapeutic action as santalol, of which it contains seventy-two per cent., and not to cause eructation.

Sodium Vanillate and Cocaine.-A combination that is reported to be of special service for dental and other minor surgical operations is a combination of sodium vanillate and cocaine in solution. Sodium vanillate acts as a local anæsthetic and exerts a vasodilator effect, while cocaine has a vasoconstrictor action. It has been found that when a solution of sodium vanillate and cocaine is employed, the anæsthetic action of the cocaine is increased and its vasoconstrictor properties are modified. The union of both bodies is said to form a double chemical compound. The following formula for the combination is from a French source, the verbena water ordered in it being intended as a preservative: Cocaine alkaloid, gr. 1/6; sodium vanillate, gr. 1/6; verbena water, minims 15.

Army Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Army for the week ending September 5, 1908:

ARTHUR, W. H., Lieutenant Colonel. Appointed a member of the examining board to meet at Washington, D. C., for promotion of medical officers.

ASHFORD, M., First Lieutenant. Ordered to proceed from Washington Barracks, D. C., to camp of instruction, Fort Benjamin Harrison, Ind., and rejoin Company C, Hospital Corps

BAILY, H. H., Captain. Ordered, in addition to present duties at Fort Myer, Va., to make the necessary sanitation to present duties at Fort Myer, Va., to make the necessary sanitation to the clarifold. tary inspection of the rooms occupied by the clerical force of the War Department, during the absence of Major Paul F. Straub, Medical Corps

BIRMINGHAM, H. P., Lieutenant Colonel. Relieved from duty as a member of the examining board for promotion of medical officers, to meet at Washington, D. C.

Brewer, I. W., First Lieutenant, Medical Reserve Corps. Granted thirteen days' leave of absence.

CARTER, W. F., Major. Leave of absence extended one

COFFIN, J. M., Captain. Leave of absence extended one month.

DAYWALT, G. W., First Lieutenant, Medical Reserve Corps.
Ordered to proceed from the Depot of Recruits and Casuals, Angel Island, Cal., to the Presidio of San

Francisco, Cal., for temporary duty.

Jones, H. W., First Lieutenant. Granted three months' leave of absence, to take effect about January 15, 1909, upon the arrival of the transport Buford at Manila, He is authorized to return to the United States via Asia and Europe.

Mason, C. F., Major. Appointed member of a board of officers to meet at Pittsburgh, Pa., for the purpose of examining the plant for the purification of water by ozone now in operation at the Homeopathic Hospital in that city.

RHOADS, T. L., Captain. Orders for examination for promotion at Manila, P. I., revoked.
ROBERTS, E. E., First Lieutenant, Medical Reserve Corps.

Relieved from duty at Fort Logan H. Roots, Ark., and

will proceed to Fort Sill, Okla., for duty.

Wertenbaker, C. I., First Lieutenant, Medical Reserve
Corps. Relieved from duty at Madison Barracks, N. Y.,
and ordered to Fort Wadsworth, N. Y., for duty.

Navy Intelligence:

Official list of changes in the stations and duties of officers of the medical corps of the United States Navy for the week ending September 5, 1908:

ELY, C. F., Passed Assistant Surgeon. Detached from the Hartford and ordered to the Charleston.

HAYWARD, A. B., Assistant Surgeon. Detached from the

Marine Recruiting Station, Pittsburgh, Pa., and or-

dered to the National Recruiting Station, Dallas, Tex. MAYERS, G. M., Passed Assistant Surgeon. Granted sick leave for three months, when discharged from treatment at the Naval Medical School Hospital, Washing-

ton, D. C.

Moran, C. L., Assistant Surgeon. Detached from the
Naval Recruiting Station, Dallas, Tex., and ordered to
take a course of instruction at the Naval Medical
School, Washington, D. C.

Births, Marriages, and Deaths.

Koerper.—In Washington, D. C., on Friday, August 28th, to Captain C. E. Koerper, Medical Corps, United States Army, and Mrs. Koerper, a son.

Married.

BLOODGOOD—HOLT.—In New York, on Tuesday, September 1st, Dr. Joseph Colt Bloodgood, of Baltimore, and Miss

LEVINGS-REILLY .- In Milwaukee, Wisconsin, on Sunday, August 27th, Dr. A. Hamilton Levings and Miss Grace Marion Reilly.

Long-Susser.-In Buffalo, on Friday, August 28th, Dr. H. C. Long, of Cleveland, and Miss Lillian L. Susser.

Albright.-In Hatfield, Pennsylvania, on Sunday, August ALBRIGHT.—In Hatheld, Pennsylvania, on Sunday, August 30th, Dr. I'tlus Albright, aged forty-eight years.

Andrew.—In Vineland, New Jersey, on Monday, August 31st, Dr. A. C. Andrew, aged ninety-three years.

Bartholomew.—In Denver, on Thursday, August 24th, Dr. H. B. Bartholomew, aged forty years.

Bowen.—In Chicago, on Tuesday, August 29th, Dr. Mary

H. Bowen, aged seventy-four years.
GARDNER—In Fulton, Kentucky, on Friday, August 25th.
Dr. John L. Gardner, aged sixty years.
Hodge—In London, Ontario, Canada, on Saturday,

August 26th, Dr. George Hodge, aged sixty-eight years.

Honge.—In Henderson, Kentucky, on Sunday, August 27th, Dr. Joseph Anthony Hodge, aged seventy-nine years. Holt.-In Philadelphia, on Monday, August 31st, Dr.

Jacob Farnum Holt, aged seventy-seven years.

Johnson.—In Grand Rapids, Michigan, on Thursday,
September 3d, Dr. George K. Johnson, aged eighty-six

Neel.—In Gloucester, Massachusetts, on Monday, August 31st, Dr. William D. Neel, of Chicago, aged fifty-eight

years.
Phillips.—In Goshen, New York, on Tucsday, September 1st, Dr. Edgar L. Phillips, aged eighty-one years.
Rustin.—In Omaha, Nebraska, on Wednesday, September 2d, Dr. Frederick T. Rustin, aged thirty-seven years.
Saykes.—In Eckman, West Virginia, on Thursday, September 3d, Dr. A. H. Sayres, of Bluefield, West Virginia.
Washburn.—In New York, on Thursday, September 3d, Dr. U. Leroy Washburn, aged fifty-nine years.
Wheelers.—In Wolf Lake, Michigan, on Tucsday, August

WHEELER.-In Wolf Lake, Michigan, on Tuesday, August 20th, Dr. Legrand Wheeler, aged seventy six years

THE EXPLOSION OF THE THEORY OF HEREDITY.

By A. Lapthorn Smith, B. A., M. D., M. K. C. S. (England),

Montreal, Canada,

Surgeon in Chief of the Samaritan Hos ital for Women: Gyn.ecc' gist to the Western General Hospital; Formerly Professor of Gynæcology in the University of Vermont, etc.

It was quite natural that the people of three thousand years ago should have thought that all the qualities and accidents which befell the race were due to hereditary transmission. They saw the offspring of each animal and plant around them resembling its ancestors down to the most minute details, while the changes which took place in any species as the result of altered environment, such, for instance, as the loss of the hind legs of the whale and the seal when they became water animals, occurred so slowly that they were not able to observe them. Even in our own time, when breeding of animals has become a science, and when a colt can be produced with extremely thick, strong legs, for going slowly, or long and thin ones for great speed, and a cow can be produced which will give a large quantity of milk or cream, according to the breed of the father, it is no wonder that people have grown to think that everything depends on heredity, and that little or nothing depends on environment. idea, which is quite correct and of great commercial value when applied to the breeding of plants and animals, is quite erroneous and most unfortunate when applied to mental and physical disease. The idea, for instance, that tuberculosis was hereditary and unavoidable has cost millions of lives which are now being saved because the whole world has discovered that the disease is contagious and preventable. But this change in opinion did not come by chance; indeed, it was opposed by many of the ablest pathologists long after it had been generally accepted by the profession and widely suspected by the public. Those who stoutly maintained that tuberculosis was contagious had to swim against the stream of medical opinion long after Koch had discovered the contagious bacillus. The same thing exists now with regard to cancer as existed twentyfive years ago with regard to consumption. The insurance companies, which employ thousands of doctors to eliminate hazardous lives from their business, have laid great stress on the importance of inquiring into the heredity of the applicant, but have never asked any questions as to their having been

exposed to the contagion of consumption and cancer. While a wonderful and beneficent change has come over public opinion with regard to consumption, the views held as to cancer and insanity have remained almost where they were a hundred or two hundred years ago. And yet I believe that I can prove that cancer is not hereditary at all, any more than insanity and drunkenness are, and to remove the mental suffering of those whose parents have acquired these diseases is the principal object of this paper. Moreover, as long as cancer, insanity, and drunkenness are believed to be hereditary, no efforts will be made to prevent them. Those who have had such parents will simply sit down and fold their hands and wait for the inevitable blow to fall upon them.

Let us, then, begin with an inquiry as to the cause of cancer. That it is worth while inquiring into is evident from the fact that, according to the census of 1890 it destroyed 18,536 lives in the United States alone. Ten years later the number reached 29,475, or nearly one third more. One out of every twelve women who die after forty-five and one out of every twenty-one men are killed by it. In the whole of the United States it killed in the year 1900, 11.346 men and 18.039 women. All over the world, in fact, it has increased about thirty per cent. during one decade. What is responsible for this awful sacrifice of human life? Without hesitation I must say that it is due to the terrible mistake which has been made of considering as hereditary and unpreventable a disease which is highly contagious, and which, consequently, could be eradicated from off the face of the earth within the next ten or twenty years. One of the first steps, therefore, is to educate the public out of this most unfortunate tradition of heredity.

It is strange that the contagiousness of cancer has not made more headway during the last twenty years, for such men as Shrady, of New York, and McEwan, of Glasgow, so long ago as twenty years. said: "Cancer is essentially a local disease, and the opinion that it is a constitutional or hereditary one is productive of the most dire results." The writer, during the last thirty years, whenever he has met with a case of cancer, has taken great pains to ascertain whether the father and mother of the patient had suffered from it; the result of his inquiries has been that it was quite the exception to find any sign of heredity. In order to ascertain whether other practitioners had had the same experience he wrote to several medical journals asking their readers to communicate with him on this point. Fifteen physicians replied, giving reports of over fifty cases of death from cancer in their practice, not one of which had a cancerous father or mother, or even a grandfather or grandmother who had died from cancer. Another doctor wrote: "I do not think one case in ten of mine had an immediate ancestor affected with the disease." I have already said that the insurance companies had done a great deal to propagate the hereditary theory of cancer. And yet it would pay them to recognize its contagiousness and so to see cancer stamped out. Among my correspondents was a medical director of an insurance company, who stated that from 1858 to 1905 the company had lost from cancer 1,361 insured, after having refused from their business all those who had had an ancestor die from it. These deaths represented a loss of at least \$1,361,000. In the year 1904 this company lost 113 persons from cancer. As a result of the writer's letter the medical director of this company has sent the following circular to the physician in care of each case dying from cancer, to answer and return to the office:

1. Have any other members of Mr. ——'s family died of cancer? If so who? 2. Was Mr. —— brought in contact with any one suffering from cancer prior to the beginning of his last

ticulars.

4. As far as you can ascertain, have there been any other cases of cancer on the same street and in the vicinity

of the house in which Mr. — died?

5. Are there any reasons in your mind to suppose that the cancer which caused Mr. — 's illness was caused by an infectious process? If so, kindly state reasons.

The writer cannot too highly commend this circular, which, sent out to several hundred physicians who have attended cancer cases, will at least set them thinking, and they cannot think about it very long without arriving at the conclusion that the heredity of cancer is a fallacy which is no longer tenable. If the medical director of every insurance company in America and Europe would follow this one's example and at the same time have inserted in the application for a policy the question, Did you ever live in a house or come in contact with any one who died of cancer? it would soon become generally known that the disease was contagious, and steps for isolating it would be taken accordingly, thereby saving the insurance companies millions of dollars and the country thousands of lives.

Although Sir James Paget, in his Morton lectures in 1887, just twenty years ago, said: "I believe that microparasites, or substances produced by them, will some day be found in essential relation with cancers and cancerous diseases"; and although since then cancer commissions in different countries have been working steadily on the problem, we are not yet able to state positively, although the writer believes, that cancer is due to the presence of an amœba, a microscopic animal found at the bottom of ditches, ponds, and pools of stagnant water. This would explain why cancer is more prevalent in low lying and badly drained localities. The amœba, when dry, draws in its pseudopodia and shrinks up into a minute speck of dust, but when placed in a warm and damp environment it comes out of its state of hibernation and begins its activities again. These consist in throwing out a sucker or pseudopodium into a neighboring cell, the protoplasm of which it immediately begins to appropriate. By the time the cell is emptied of its contents the amœba has passed entirely into it and is ready to extend its pseudo-podia into other cells to be destroyed in the same way. After having become particularly strong and vigorous it may send out as many as three pseudopodia into as many different cells at the same time.

Eisen, of San Francisco, has called these amœbæ cancriamæbæ macroglossæ. He says they measure from seven to thirty micra in length. These cancriamœbæ having gained entrance to the system, either through the alimentary canal, or, as is more probable, through an abraded surface, may remain a long time in the incubational stage without manifesting their presence. They may be circulating in the blood of many of us, but as long as every cell in our bodies retains its normal vital resisting power they will withstand all attacks from the cancriamœbal forces. But let the vitality of a part be lowered by an injury or a bruise, or subjected to a constant irritation like a clay pipe on the lip, or exhausted by constant warfare against chronic inflammation, the cells become weakened in their vital resisting power to the extent that they cannot longer repel the attacks of the enemy, and the disease has commenced. This is exactly what we know about the behavior of the tubercle bacillus: a rapidly growing boy, anæmic from deprivation of sunlight and proper food, or sufficient time in which to eat it, receives a blow on the hip or knee which lowers the vitality of the part, and at once the tubercle bacilli, which had already entered his blood by his stomach or by his lungs, take on a rapid growth which may destroy the joint or even his life.

Let us now consider what Nature does to resist this invasion of her domain. When any point is threatened she calls her forces to her defense and puts forth her utmost energy to guard her borders. So in this case, as soon as a cancriamceba commences to prey upon an epithelial cell the neighboring cells take on an increased activity, rapidly multiplying and becoming gigantic in their dimensions. This is the cell proliferation so noticeable in the vicinity of malignant tumors. The active and growing cells press on those near the cancer nest from without, while growing and multiplying cancriamcebæ are crowded upon them from within. The result is that they become flattened and lunated; at the same time the cell wall or membrane of those nearest the cancer nest take on a chitinization the more readily to hedge in and prevent the cancriamæbæ from reaching out and penetrating their walls to feed on their contents. Perhaps it would be more proper to say that this chitinization or hardening is part of the life history of the amœba, for it is due to a calcareous secretion thrown out by the amœba itself, for the amœba is frequently covered with it. Thus is formed that stony hardness which is so characteristic of cancer, and, as every one has observed, the harder the cancer the slower the growth, other things being equal. According to Eisen, this cell proliferation, so pronounced in carcinoma, has been called the disease. The mistake has been that we have considered the manifestation which Nature makes to stop the disease as the disease itself.

But, as Eisen says: "The cancriancebæ more often triumph over cell activity. The fortress of chitinization is seldom sufficient to withstand the pseudopodial battering rams of these organisms. Wall after wall of the best fortified cells are penetrated and crumble down, and in the débris thus formed leucocytes begin to appear, as they always do, in the waste tissues of the body if retained in the system. The hitherto hardened mass begins to soften in the centre, and soon the open ulcerative surface appears-the veritable battlefield of microscopic hosts strewn with the dead and dying of both sides, to be consumed by the leucocytal vultures." This, however, is not always the result; sometimes cell life is so vigorous and active that the cancriamebæ are effectually imprisoned in their cornificated walls and die from inanition. The growth then diminishes in size and the hard tumor which we thought was going to be a malignant disease remains stationary as a small tumor for years. This is one of Nature's methods of curing a cancer. It is similar to the cure of tuberculosis of the lungs, where Nature, aided by a well directed therapeutic effort, has succeeded in throwing up a wall of calcareous material around a nest of tubercle bacilli, as is frequently revealed by autopsy years afterward.

To sum up: The bubble of the heredity of consumption has been burst and requires no further argument. Cancer, which has been considered a hereditary disease, is largely on the increase, just as consumption is on the decrease. One of my correspondents, the medical health officer of the model town of Bernardstown, Mass., in which every death has been recorded, with its cause, since 1864, writes me as follows: "From 1864 to 1874, one death from cancer, and forty from tuberculosis. From 1874 to 1884, three deaths from cancer, and twenty-six from tuberculosis. From 1884 to 1894, eight death from cancer, and seventeen from tuberculosis. From 1894 to 1904, twenty deaths from cancer, and seven from tuberculosis." Simply because cancer is still believed to be hereditary and no precautions are taken toward stamping it out, while consumption is recognized to be contagious and is being rapidly stamped out. So that it is of the utmost importance that the popular idea of its heredity should be changed; for until it is, no steps will be taken to isolate it and people will put off having it removed while it is still possible to remove it entirely.

Cancer is an absolutely local disease in the beginning, and should be removed at the earliest possible moment after its presence is *suspected*.

The amœba of cancer may remain dormant a long time in its dry state and take on activity under suitable conditions. A room or a house vacated by a cancer case should be most carefully disinfected before being again occupied. Several of my correspondents have reported cases contracted from a cancer house. Just as in tuberculosis, people may be exposed to the contagion many times without contracting the disease, because their cells are in good condition and able to destroy or resist the amœbæ, but when they get older and their cells are less vigorous, the amoebæ will conquer their cells and the disease will soon be in full blast. As scar tissue and ulcerated surfaces are less able to defend themselves than normal tissues, the possibility of cancer should be kept in view when these conditions are present, especially in people nearing forty. Scar tissue and

chronic ulcers should be removed, when possible, before cancer has had time to infect them. And for the same reason no dietetic sacrifice is too great to be worth while making if it is necessary for the cure of dyspepsia, which is the commonest cause of ulcers and scars in the stomach.

Want of space and other reasons preclude my giving, even in brief detail, the instances of cancer having been acquired by contagion; they have been published in the *International Journal of Surgery* for December, 1906. I do not think anybody could read them without being convinced that cancer is

contagious, for in not one case had either parents or

grandparents suffered from that disease.

Let us now take up another gigantic bubble, the heredity of insanity, which cannot be exploded too soon. What misery has been entailed upon perfectly healthy people by the ever present spectre overshadowing their lives, that their mother or their grandfather or their aunt was insane. This heredity of insanity has been so much abused in making statistics that on this point they are quite unreliable. For instance, the son of a clever man marries, has a large family, quarrels with his wife, leaves her, contracts syphilis, gets a gumatous tumor on the brain, and goes to the asylum. His very clever daughter marries and has uræmic convulsions with her first child and also becomes insane. Evidently these two casees of insanity have absolutely nothing whatever to do with each other, and yet her case would surely be classed as hereditary, because her father died insane. Here, again, insurance companies and the superintendents of insane asylums have handed down this false tradition from generation to generation, so that the profession, and the public through them, have been trained to believe that it is true. On the contrary, I am convinced that a child born of the most clever and most intellectual parents may become insane, if improperly fed or badly brought up, while a child of weak minded, or even insane, parents may grow up to be an intellectual giant if transplanted soon after birth to a highly intellectual environment and if properly fed. Idiots and those having organic disease of the brain are not referred to at all in this paper. As for the brains of the insane, the writer states that our brains are just what we make them by exercising, cultivating, feeding, starving, and poisoning them. If his contention can be proved, a great deal of what has been copied from one textbook into another for the last fifty years will have to be abandoned, with the result that thousands of people who are now regarded as hopelessly insane because of supposed heredity, will be treated and cured and restored to their family and friends.

Taking any hundred women in any asylum at random, an unbiased investigation of the cause of their insanity will enable us to group probably ninety-five of them under one of two headings; first, those caused by defective nutrition of the brain, and second, those caused by poisoning of the brain. Under the first heading we must place those women whose brains are starved by reason of insufficient food or light or air; second, those whose blood cannot nourish the brain because of increased demands upon it, such as lactation, pregnancy, insomnia, or exhausting hæmorrhages; third, those in whom the brain is starved, because some great mental impres-

sion so affects the sympathetic nerve as to take away the inclination for food, and to prevent its digestion if eaten; and fourth, those whose brains are starved because some abnormal pelvic condition is irritating the sympathetic, which irritation is expressed in the brain by contraction of the circular fibres of the arterioles; so that no matter how rich the blood may be, an insufficient supply of it is able to reach the brain cells. In the category of insanity from poisoning, we must include cases of autointoxication by ptomaines and from defective digestion and assimilation, whereby the proteids do not reach the ultimate stage of urea, but stop at the formation of creatin, creatinin, xanthin, or uric acid; second, the cases of defective secretion by the liver and kidneys, so that poisons such as bile and urea accumulate in the blood and inundate the brain cells, instead of being removed as fast as they are produced; third, insanity after operations, which if not due to iodoform should rather be called septic delirium from blood poisoning.

Let us now look a little more carefully into the bearing of each of these conditions as a factor in the

causation of insanity.

Starvation of the brain due to anæmia. Every practitioner of twenty years' experience can recall many cases, mostly in young women, in whom the brain failed to work correctly from this cause. One of the first cases of insanity which came under the writer's care was a young woman who became violently insane owing to a disappointment in love, and who had to be sent to an asylum. How did the brain become starved in this case? The process is easily explained; any all absorbing passion of occupation takes away the appetite and even paralyzes the function of digestion. This young girl was so much in love that for nearly a year before she had had no time or inclination for food, and her blood became anæmic. When the disappointment came she absolutely refused to eat, and a few days later her brain had become so entirely deprived of nourishment that reasoning came to a standstill. Since then the writer has seen many cases of this kind, in varying degree and from different causes. At one time it has been a woman with uncontrollable vomiting, who became more and more anæmic from starvation until the mind wandered. Another time it has been a wife who had been so plunged in grief from the death of her husband that she could not eat. The insanity is only temporary in all these cases, for as soon as food is eaten and digested, the brain rapidly recovers its functions. Under the same heading may be classed the insanity of pregnancy and lactation; the brain cannot work properly without phosphates, but these are taken up to such an extent to provide bones for the child that the mother's brain is deprived of them. As soon as phosphates are furnished in abundance the woman rapidly regains her

The importance of sunlight and fresh air is well known, but its bearing upon insanity is perhaps not so well understood. And yet we may safely say that the brightest and happiest woman would eventually become melancholic and even insane if she were kept in a room from which every ray of sunlight had been excluded. The superintendent of a large and successful sanatorium states that patients who are

despondent almost to the verge of committing suicide, show the most remarkable improvement within a few days after being placed all day in the sun parlor. Many of the mild cases of insanity which are cured in sanatoriums, principally by sunlight, fresh air, and nourishing food, would probably otherwise have found their way to the asylum.

It is interesting to note that Dana attributes the insanity of women at the menopause to starvation of the brain cells, owing to senile degeneration of the arterioles, which diminishes their calibre, and consequently allows less blood to pass through them. If such was the case, little or nothing could be done for these patients. But it bears on our subject to remark that Skene, who has given this subject much attention, states that in his experience the insanity was due to overwork, childbearing, and lactation, with insufficient food and sleep. How often do we find just such conditions among the farmers' wives, who contribute such a large contingent to the insane asylums.

Insanity from poisoning of the brain. It will be convenient to subdivide the causes of the poisoning under four heads: 1, poisoning from defective action of the kindneys; 2, from defective action of the liver and bowels; 3, from defective assimilation or combustion, so that chemical products are formed in large quantities, which should not be formed at all or at most only in very small quantities; and 4, from septic poisoning. Insanity is a well known termina-tion of disease of the kidneys, but the discussion of it is more suited to a technical journal. But the second cause, autointoxication, is so common that it should be better understood. The writer fully believes that the systematic keeping clear of the intestinal tract would save hundreds from the asylum and reclaim hundreds of thousands from that semiinsane state known as melancholia. The word itself expresses the condition. The failure of the liver to keep the blood free from black bile keeps the patient constantly on the border of insanity. Their intense despondency frequently leads them to suicide. A course of cholagogue cathartics, and the correction of the diet so that the intake shall not greatly exceed the output soon makes a marked difference in their mental condition. One patient, who did not know her husband and refused to recognize him, completely regained her sanity after a month of such a treatment, so that she was able to return to her home and take care of her house, although previously she had to be taken care of by a trained nurse.

Contagiousness of insanity. I have already expressed a strong conviction that insanity was not hereditary; if it were so a much larger proportion of those now in the asylum would have had insane parents; not insane uncles and aunts, but insane parents. Moreover, it is not logical to sav that everything which happens to a person is hereditary because it happened to his father and mother. It was also stated that in insanity, as in consumption, the idea that it was hereditary has been one of the greatest obstacles to treatment, so that, insead of being one of the most amenable, it has come to be considered one of the most hopeless. "If it is hereditary," people say, "then it is bound to come no matter what they may do. Therefore why do anything?" Believing that heredity was one of the factors which had least to do with it, the writer was pleased to notice an article by Dr. Vallee, superintendent of the Beauport Asylum, Quebec, that he believes that many cases of insanity are contagious, in the sense that one member of a family may by imitation of the insane actions of another member gradually become as insane as the first one.

Explosion of the theory of the heredity of drunkenness. This too prevalent disease is generally supposed to be hereditary. But the writer is convinced that what has been taken for heredity is simply a matter of imitation. He knows of several families where the father was a confirmed drunkard long before the children were born, and yet not one of those children care for alcohol; in fact, they loathe it. These children were for the most part educated away from home. In another family, where the father only took to drink after all the children were born, the five boys were brought up with the constant example of a drinking father before them, and four out of the five have become drunkards. If drunkenness was recognized as contagious instead of hereditary many a family might be saved from this disease, either by isolating the drunken father or by sending the children away when practicable.

If more attention were paid to training and environment and less to heredity, there would be fewer consumptives, fewer people with cancer, fewer insane, fewer drunkards, and fewer murderers.

238 BISHOP STREET.

ISCHOCHYMIA.*

By Frank Hall Murdoch, M. D., Pittsburgh, Pa.

Ischochymia is an affection characterized by the constant presence of food in the stomach, even in the fasting state (Einhorn). It may be acute or chronic. Whether acute ischochymia or acute dilatation of the stomach, as it is termed by Boaz, Hunter, and others, is due to a paralysis of the gastric muscles, or to a spasmodic contraction of the pylorus, or to both, is as yet undecided. It is usually brought on by some gross error in diet, though it occasionally follows chloroform anæsthesia. Out of sixty-four cases known, forty-seven proved fatal. Of the total number of cases, twenty-nine followed chloroform anæsthesia, and in eleven of these the operation had not involved the abdomen, but was at points remote from it (Neck).

The chronic form is caused (I) by mechanical obstruction of the pylorus, (2) by absolute or relative weakness of the expulsive forces—in other words, atonic conditions of the muscularis. The mechanical factors which lead to stenosis or occlusion of the pylorus are either situated in the wall of the stomach itself or extend to it from without. The most frequent causes of the former are carcinoma and cicatricial contraction from an ulcer situated near the pylorus, or spasmodic contraction of the pylorus from the same cause. There are cases too in which hypersecretion of gastric juice has so to irritated the mucus membrane of the stomach as to cause spasmodic contraction of the pylorus with

temporary stagnation of food in the stomach, and should this condition continue long enough, it may finally lead to muscular hypertrophy.

The causes situated external to the stomach which may produce stenosis or occlusion of the pylorus are tumors arising from the pancreas, the omentum, the retroperitoneal glands or the liver, adhesions of the pylorus to neighboring organs, or cicatricial bands, which make traction or pressure on the pylorus. Bartels was the first to call attention to the joint occurrence of wandering right kidney and dilatation of the stomach, but Oser, Nothnagel, Leube, and Ewald believe that no causal relation exists in the majority of cases, and Kutner has shown that in many cases of so called dilatation with floating kidney, there is no dilatation, but either a megalogastria or a gastroptosis, which has led to erroneous conclusions (1).

Stenosis of the pylorus is always associated with hypertrophy of the muscular wall of the stomach, just as an aortic or mitral stenosis is accompanied by hypertrophy and dilatation of that portion of the heart situated behind the obstruction. Also in the later stages of advanced dilatation, the musculature, though hypertrophied, may become so weakened that all peristaltic movements may cease (2), just as rupture of compensation occurs in long standing cases of dilatation of the heart due to obstruction at

one of its openings.

Most authorities distinguish two degrees of ischochymia. In the morning if food is found in the stomach which had been taken the previous evening, this is considered to be a high degree of ischochymia. If, on the other hand, the stomach is found to empty itself during the night, but contains particles of food seven hours after a test meal, this is said to be a mild degree of ischochymia. Ischochymia due to atony of the stomach walls is comparatively rare, and an exact diagnosis is at times very difficult. If we have a case of ischochymia, where a thickening of the pylorus can be palpated, and also where peristaltic restlessness can be seen, then the case is clear; but if neither of these signs is present it is not easy to say whether we have before us a case of obstruction of the pylorus of long standing with resultant loss of peristaltic movements of the stomach, or whether we have such a loss of motility from atony of the gastric musculature as renders the stomach inadequate to transport its contents through a normal pylorus.

Usually in ischochymia resulting from stenosis of the pylorus, only the coarser particles of food are found in the stomach in the morning before the patient has eaten anything, the finer particles and the liquid contents having passed into the intestines. On the other hand, where stagnation of food is due to atony of the gastric musculature, the coarser particles of food will pass through the pylorus and only a small quantity of the finer particles mixed with liquid chyme will be found in the stomach in the morning before the patient has taken any food. In the treatment of ischochymia due to mechanical obstruction of the pylorus, surgical interference is demanded if the obstruction is due to malign stenosis, to benign stenosis of high degree which will not yield to medical treatment, to adhesions of the pylorus to neighboring organs, to cicatricial bands,

Presented at a meeting of the American Gastroenterological Association at Chicago, June 1, 1908.

or to tumors which by pressure obstruct the outlet of the stomach. Formerly operation was considered necessary in all cases of benign stenosis of the pylorus of whatever degree, but now we know that such is not the case, for under proper medical treatment, including diet and lavage, many patients entirely recover. If we have a patient who has a stenosis of the pylorus of such degree that solid food will not pass out of the stomach in the normal time, but will pass out in twelve or fourteen hours, we can allow that patient two meals of solid food each day, one in the morning, the other in the evening, and direct that liquid food be given between meals in sufficient quantity to make up the necessary number of calories. If the stenosis is of such degree that a test meal of solid food remains in the stomach for a longer time than twelve or fourteen hours, then liquid food only should be allowed for a time, the stomach meanwhile being washed out every morning before the patient has taken any food. So long as the patient can, under this treatment, maintain his strength and weight, and is willing to live in this way, operation should not be urged, because there is always a hope of complete recovery without surgical intervention, and should the patient begin to lose ground in spite of these measures, an operation can be done at any time. Stenosis of the pylorus which occurs in wasted infants, at least that due to spasm, also seems quite amenable to medical Bloch has recently reported twelve cases. The first six infants were treated with gastroenterostomy and four died. The last six were treated by medical means and recovered. In the fatal cases the pylorus was always found closely contracted, but the evidence, he thinks, tends to show that when this spasmodic contraction is overcome the normal lumen of the pylorus is permanently restored (3).

Robert Hutchinson also reports nine typical cases of congenital stenosis of the pylorus seen by him during the winter of 1905 and 1906, all of which recovered under medical treatment. In two of the cases the condition seemed at one time to be so desperate that operation was advised, but was not performed because the parents refused to sanction it; yet both children ultimately got well. He therefore states his position as follows: (1) Operation is never justifiable as soon as the diagnosis of congenital pyloric stenosis has been made. (2) One can never be sure that medical treatment is going to fail until the condition of the child is already so bad that the chance of recovery after operation is almost nil. He believes with Bloch, that the stenosis in these cases is the result of spasm which leads to a secondary hypertrophy of the pylorus, and that this hypertrophy disappears as the spasm passes off (4). Miller and Wilcox (5) likewise believe that the medical treatment yields the best results, and are of the opinion that those children who die under medical treatment die with diarrhœa, because the intestine has become too atrophic to deal with the food which passes into it when the pyloric spasm has been relaxed. As additional evidence showing what may be done by medical means for the relief of benign stenosis of the pylorus in adults, I wish to report the following cases. In one case the stenosis followed the healing of a chronic gastric ulcer; in the other case the pathogenesis was obscure:

Case I.—On October 24, 1902, Miss H. N., aged twenty-unconsulted me and gave the following history: In March, 1901, she began having pain in the epigastric region immediately after meals, with nausea but no vomiting. This attack lasted eight months, or until January, 1902. During the winter and spring of 1902 she enoyed good health, excepting that she did not feel very strong. In July of the same year she had an attack of cholera morbus, and has had pain in the epigastrium ten or fifteen minutes after meals ever since.

Present condition: Pain soon after meals made worse by moving about, nausea but no vomiting. Often had a bowel movement after a meal, bad taste after eating, appetite good, but never experienced a sense of having had enough food, felt sleepy during the day, but did not sleep well at night, bowels rather constipated; had lost thirteen pounds in weight, now weighed one hundred and ten pounds.

Examination: Heart, lungs, and liver normal. Stomach splashing to navel, right kidney in third degree of displacement, one tender circumscribed spot, two inches above the navel in median line, also a tender spot in the back to the left of the lower dorsal vertebra. Examination of the stomach content, taken an hour after Ewald's test meal, showed that free hydrochloric acid was absent, total acidity 60. Urine was 1.018 specific gravity and contained neither sugar nor albumin.

Treatment: Rest in bed, liquid food, principally buttermilk, and silver nitrate in pill form.

This patient remained in bed three weeks and lived on liquid food for three months, at the end of which time she was permitted three small meals of solid food each day with liquids between. At this time I also made a second examination of the stomach content after an Ewald test meal and found free hydrochloric acid, + 44, total acidity 64.

ity 04.

In November, 1903, she complained of pelvic pain, and Dr. Werder found that her uterus was retroverted and fitted her with a suitable pessary, which gave her relief.

In July, 1904, a year and eight months after I first saw her and fifteen months after commencing to take solid food, she began to suffer from a stenosis of the pylorus, due evidently to contraction or spasm of the tissues at the site of the ulcer, and in spite of the usual treatment the ischochymia persisted for eleven months, or until June, 1905. The stomach then emptied itself normally for six months, or until January, 1906, when the ischochymia again appearing, an operation was strongly advised, but the patient preferred to go on with medical treatment as long as possible; and this attack also yielded, for in June, 1906, she wrote that she had taken a test meal of beefsteak, potatoes, bread, and butter, and on washing out the stomach seven hours afterwards, had found it entirely empty. In February of this year Dr. J. B. Neale, her family physician, informed me that the patient's health was good and that there had been no return of the stenosis.

In regard to the frequency with which stenosis of the pylorus occurs as a result of chronic gastric ulcer, Brinton has computed that severe stenosis occurs in one out of every two hundred cases, and Fenwick believes that the pylorus becomes partially occluded in sixteen to twenty per cent. of all cases; but that in only about two per cent. of these is the stenosis extreme. The case I have related is one of thirty-two cases of chronic gastric ulcer previously reported, and the only one in which stenosis of the pylorus occurred, being 3.1 per cent. (6).

Case II.—On July II, 1904, Mr. C., aged sixty-two, bookkeeper, was referred to me by Dr. R. W. Stewart, who had diagnosticated stenosis of the pylorus, but the patient wished to avoid operation if possible. The history of the case is as follows: Two years ago he began to be troubled with bloating and belching coming on soon after meals, and also distress in the epigastrium about an hour before each meal, which was relieved by eating. He also suffered from severe attacks of pain in the abdomen, which came on about 4 o'clock in the morning. He had never taken morphine to relieve these pains, but was in the habit

of drinking hot water and applying a mustard plaster to obtain relief. He had lost twenty-five pounds in weight, and felt weak and discouraged. His appetite was good, his bowels regular, and he slept well when free from attacks of pain. Inflation of the stomach showed that lower border extended three and one half inches below the umbilicus. Free hydrochloric acid was present in normal amount. The specific gravity of the urine was 1.010, and it contained neither sugar nor albumin. He took a test meal in the evening, and the next morning before he had eaten anything I washed out his stomach and found part of the food he had taken the previous evening, together with numerous berry seeds he had eaten the day before. Lavage was practised every morning after this and berry seeds appeared in the wash water until the 15th inst., that is, four days after they had entered the stomach. addition to lavage the treatment consisted in allowing the addition to lavage the treatment consisted in allowing the patient only liquid food, and the method proved so satisfactory that on December 6, 1905, about five months after I had first seen him, he had gained nineteen pounds in weight and felt strong and well. He was then taking two meals of solid food a day, one in the morning and the other in the evening, with liquids between to make up the necessary number of calories. He occasionally washed out his stomach in the morning, and always found it empty. I saw this patient in January, 1906, a year and a half after he first consulted me, and he was then in good-health; I also heard directly from him three weeks ago, and he was still in good health and so far had not required surgical aid.

There is no doubt that gastroenterostomy would be the ideal treatment for all cases of benign stenosis of the pylorus if it were entirely free from danger, but so long as even a small percentage of patients die as a result of this operation it is the duty of the physician to employ every available means for the patient's relief before advising surgical intervention.

CANCER OF THE RECTUM.

A Study of One Hundred Consecutive Operations for Malignant Growth of the Rectum and Sigmoid.

BY JAMES P. TUTTLE, M. D., New York.

(Continued from page 504.)

CASE XXXVI.-March 14, 1901. Mrs. G. H. A., age thirty-two

Family history was clear.

Eight or nine months ago noticed passage of a little blood at stool; morning passages of mucus; six to ten passages a day. Cutting pain when bowels move. Anus normal. Three and one half inches above the anus a hard protruding tumor extended up beyond reach, on the anterior wall of the gut, posterior wall clear. Adeno-

March 21st. Bone flap operation; resection six inches end to end suture of cut ends; sutured peritonæum and boneflap. Posterior drainage. Very little hæmorrhage. March 25th. Highest temperature, 100.5° F.; doing well. April 10th. Left hospital well, except for slight posterior

May 15th. Fistula almost healed; had gained ten pounds, and felt well.

March 30, 1903. Fistula healed in August, and patient went to country to live. Felt well up to one month ago, when she began to suffer from indigestion and pain in the back. Growth recurred in situ and in liver. No further operation advised

Died about six months later; condition very sad.

CASE XXXVII.-January 3, 1901. Mr. J. H. K., age Family history clear, except a sister and an uncle died of

tuberculosis

Personal history: Patient is a wiry, nervous, thin individual; weight 140, which had been his average. Constipated, no pain; had typical morning diarrhæa; no mucus or blood at stool. Sigmoidoscope showed tumor ten inches up, easily felt, in the left inguinal region. Is sausage shaped and about three inches in length.

January 10th. Operation. Resected six inches of the sigmoid, by abdominal route, Murphy button reinforced. Uneventful recovery.

Living three years after. February, 1908. Brother reports that he died in 1906, with recurrence in liver and stomach.

CASE XXXVIII.-May 16, 1902. Mrs. J. C., age thirty

Family history clear.

Patient had lost twenty-five pounds in weight in six onths. Constipated up to six months ago, since which time she had had bearing down pains and passages of mucus; morning diarrhœa or stool of mucus. Anus normal. Three and one half inches from the anus is a large, friable, nodular, ulcerating mass, extending two and one half inches up, and movable. Adenocarcinoma. Ordered salines; peroxide irrigations, and dietary preparation.

May 21st. Operated. Perineal excision. Growth large

and difficult to bring down. Vagina opened by accident.

Posterior drainage.

May 30th. Patient did well; was out of bed to-day. June 15th. Patient went home to-day; well, except for slight discharge from posterior drainage.

March 10, 1906. Marked recurrence in liver and in situ. June, 1906. Patient died. No secondary operations.

CASE XXXIX.-January 15, 1901. Mr. G. K., age fortyeight.

Family history: Sister died of tuberculosis and brother had carcinoma.

Personal history was clear. Present illness began in slight aching and frequent desire to go to stool about two months ago. Was operated upon for hæmorrhoids December 10, 1900: Now loses a little blood and mucus at stool and had morning diarrhœa. Aching and shooting pains more or less constantly. Protrusion at stool. Anus normal except for protruding mass of hæmorrhoids, one of which is polypoid, hard, nodular, and ulcerated.

January 17th. Operated, amputating lower end of rectum for about two inches. Brought gut down and sutured to skin. Pathological report, adenocarcinoma.

January 20th. Primary union.

January 27th. Left hospital well; functions perfect.

February 24, 1908. Perfectly well.

CASE XL .- April 14, 1901. Mrs. N. L. A., age forty.

Family history clear

Patient was formerly constipated. In June, 1899, passed considerable blood at stool; no pain; after several weeks bloody discharge returned, accompanied by mucus at stool; since this time bowels had been loose and constipated alternately. Early morning stools consisted of blood and mucus; pain over the lower abdomen; none on defæcation. For three months the discharge of blood and mucus had been controlled by laxatives and oil enemas. In December, 1900, was examined by a prominent practitioner in New York, who reported no rectal disease, but fæcal accumula-Advised laceration of the cervix to be repaired. During this operation rectal examination showed shaggy tumor, the size of a child's fist, surrounding the rectum and lessening its calibre. Rest in bed seemed to improve the condition, although an elevation of temperature continued, without sufficient reason in the operative field.

Examination showed no discharge or unnatural moisture about anus; sphincter tight; rectum normal for four inches; at four and one half inches up one could feel a soft, velvety tumor, which bulged out into the calibre of the gut; it was attached by a broad base, very vascular, and not indurated. Microscopical examination showed benign

papilloma. Patient deferred operation.

September 4, 1901. Tumor showed rapid progression, marked induration about base, great encroachment upon calibre of the gut.

September 10, 1901 Operation. Resection of growth by combined method. Considerable adhesions of the sigmoid to broad ligament and uterus. Operation prolonged and difficult; eight inches removed; end to end union. Patient never rallied and died from shock on the third day. Pathological report, adenocarcinoma, very malignant type.

This case illustrates very forcibly, 1, the inadequacy of digital examinations in rectal diseases; 2, the unreliability of microscopical examination of small sections of tumors; and, 3, the folly of delay in the removal of tumors of the rectum, whether benign or malignant.

CASE XLI.—November I, 1900. Mrs. M. A. F., age forty-five.

Family history was negative.

Eighteen months ago patient began to suffer from frequent stool and discharge from rectum; this continued. The discharge was dark, bloody, fætid; pain increased during the past few months and she had lost much flesh. Anus normal. Friable, nodular constriction of the rectum one inch up, extending about three inches, and contracting calibre to the size of the little finger; barely movable, if at all.

November 7th. Perineal excision. Upper part of the gut brought down and sutured to the skin. Pathological report, adenocarcinoma. Parts did not unite well; some

granulation and incontinence.

November 19th. Patient refused further treatment. Had recurrence in about nine months. Date of death unknown.

CASE XLII.-February 15, 1902. Mrs. M. M., age sixty.

Family history, clear.

Patient had had dysentery and typhoid when forty-five. Childbirths were very difficult; always constipated. Present illness began nine months ago in increasing frequency of stools; loss of blood began two months later; very little pain. Anus normal. Three and one half inches up friable, ulcerating mass, on indurated base, entirely surrounding the rectum and extending beyond the reach of the finger; easily movable, but attached to the uterus.

February 20th. Vaginal resection, seven inches of gut

removed; attachments to uterus were inflammatory and easily broken up; posterior drainage; peritonæum closed

by catgut sutures

February 21st. No shock; patient in fine condition. February 23d. Temperature, 103° F.; pulse, 120. Posterior drainage removed; considerable serum discharged.

February 24th. Temperature, 99.6° F.; pulse, 105. February 28th. Continued improvement; small posterior

fistula.

April 4th. Left hospital well, except for small posterior fistulous tract, through which no fæces escaped.

January 1, 1903. Entirely well; functions good. April 6, 1906. Still well. April, 1908. Letter of inquiry returned.

CASE XLIII.-October 10, 1901. Mr. W. G. P., age forty-two

Family history, clear.

Patient thin and aniemic; operated for piles two months ago. For three years had suffered from indigestion and loss of flesh; frequent stools with mucus; constant desire to stool; burning pain in the rectum. Skin tabs about anus, calibre normal. Rectum normal for four inches, where a hard, nodular, ulcerating tumor surrounded the gut; slightly movable; could not reach the top. Adenocarcinoma.

October 14th. Bone flap operation; resected eight inches; Murphy button reinforced; peritonæum closed; flap sutured

with silkworm gut.

Much oozing; temperature, 103.2° F. October 16th. October 17th. Much obzing; temperature, 103.22 Fr., pulse, 130; packing removed; a large amount of bloody serum dammed up above gauze. Transfused.
October 17th. Temperature 100° F.; pulse 124, better

October 10th. Temperature 99.5° F.; pulse 115. Free drainage; distinct gain.

October 20th. Continued improvement; button taken out through the anus, but fæcal fistula through posterior wound. November 25th. Patient left the hospital feeling well; fistula still losing thin fæcal matter.

February, 1904. Had been treated at outdoor clinic; fistula no longer fæcal; had gained in weight and felt well.

May 20, 1908. Remained well three and one half years, then ceased to attend clinic. Has moved and left no

CASE XLIV.-June 12, 1900. Mr. S. H., age twenty-two.

Family history was clear. Patient complained of a bloody diarrhœa, which was painless and had continued for the past two years; fifteen to twenty stools per day. Within the rectum, beginning about two inches from the anus, was a soft, lobulated tumor, which felt almost cystic, with a hard base below, and filled the rectal cavity so that it was almost impossible to

pass the finger through it. Movable.

June 13, 1900. Operated. Temporary inguinal colostomy.
Maydl method. Removed specimen. Under an anæsthetic
was able to reach the top of the growth with finger; it was

movable. Pathological report, colloid carcinoma.

June 22. Artificial anus acted well. Removed growth in rectum, boneflap method. Resected nine inches, and found I was able to bring the sigmoid down to the end of the rectum, which had been cut; end to end suture. Restored boneflap with silkworm gut sutures.

June 24th. No complications; parts seemed to be uniting

July 15th. Union complete; calibre of the rectum somewhat contracted. Closed colostomy opening, extraperitoneal method.

Patient left hospital, much improved in August' 1st. health.

July 20, 1901. Mass in abdomen suggested recurrence. July 29, 1901. Opened abdomen and found nothing but a mass of adhesions. Stricture of the rectum four inches

up. Divided by posterior proctotomy.

August 17, 1901. Stricture kept dilated; bowels now

moved freely.

August 11, 1903. Readmitted. Hernia at sight of old abdominal wound. Closed by Dr. Wellbrock; infection and prolonged convalescence; wound finally healed; no

March 1, 1908. Patient had gained ninety pounds since operation, nearly eight years ago; no recurrence.

This case is remarkable, both on account of the youth of the patient and of the colloid nature of the

Case XLV.—November 14, 1902. Mrs. M. A., age sixty-

Family history was clear.

Patient had had good health for years, except for attacks of rheumatism. Had lost much flesh in the past six months; suffered from flatulence and indigestion; for the past year had suffered from constipation; frequent call to stool, passing only "slime" and blood. Symptoms of indi-gestion and alternating diarrhœa and constipation began mine months ago. Pain in sacrum and left inguinal region. External hæmorrhoids about anus; sphincter relaxed; rectal nucous membrane congested; pelvis practically filled with a large nodular mass involving the whole circumference; movable; calibre insufficient to admit finger; mass outlined by abdominal palpation.

November 24th. Patient had been given saline every morning; liquid diet; peroxide enemas t. i. d. resection; abdominal route; tumor taken out through the abdomen; sigmoid invaginated through anus; end to end

winon accomplished. Over fifteen inches removed.

November 26th. No complications; temperature never above 100° F.; pulse highest, 95.

December 23d. Patient left the hospital.

February I, 1903. Fibrous stricture at site of union;

October 19, 1903. Patient had gained fifty pounds. Dilated stricture once a month; had a tendency to contract; no recurrence

June 1, 1908. Patient had remained perfectly well.

The specimen in this case showed a lateral anastomosis between the upper rectum and the middle loop of the sigmoid, through which all the fæces were sidetracked, leaving eight inches of the gut out of use.

CASE XLVI.-July 23, 1902. Mr. F. J., age thirty-seven. Family and personal history was clear.

Slight burning, itching, pain at the lower end of the rec tum for the past two months; had to strain a great deal when he went to stool. Anus showed large protruding hæmorrhoids; upon the upper surface of one, in the right anterior quadrant, was a hard, nodular, granular mass, elevated above the mucous membrane, and bleeding easily on touch. Rectum apparently healthy above this mass.

August 1, 1902. Local applications failed to have any effect. Operation. Excised the whole lower end of the rectum, leaving the external sphincter. Took out one and one half inches, and brought the gut down, suturing it to the skin. Induration at the base of the granular mass did not seem to involve the muscular wall. Pathological report, squamous epithelium.

August 10th. Union practically primary, no com-

August 17th. Patient left for home, practically well. April, 1906. Absolutely perfect results. May, 1908. Patient had remained perfectly well.

CASE XLVII.-July 21, 1902. Mr. W. J. S., age fifty-

Pale, grayish complexion; strident voice. No cough; always thin. Height six feet, weight 135, no recent loss of weight. Operated ten years ago for polypus of rectum. Constipated, had diarrhea and bleeding, stools flattened, required straining with solid stool; passed material resembling flaky shreds; no particular pain. Anus normal. Rectum normal for three inches, at which point was found a round, firm tumor, rather smooth, almost surrounding the gut; mucous membrane slided over it. Calibre of gut reduced to about one half.

July 27th. Operation. Extirpation by boneflap method. Resected four inches; end to end union. Very slight hæmorrhage. Closed off peritoneal cavity by sutures before opening the gut. Sutured flap in place by silkworm gut. Pathological report, small round celled sarcoma.

July 30th. Removed packing, considerable discharge of serum and blood; otherwise patient was doing well.

August 5th. Fæcal discharge largely through posterior wound.

August 15th. Fistula gradually closing. Patient left for

April, 1903. Reported himself well.

December, 1907. Still well.

CASE XLVIII.-January 28, 1903. Mr. S. K., age fortysix.

Family history was clear.

Personal history: Dark, well preserved, but tired looking man. Diarrhoeal tendency. Hæmorrhoids for many years. Present illness began after excessive exercise seven years ago. Protrusion, pain, and bleeding at stool, some swelling, which had disappeared. Large discharge of blood, mucus, and pus. Pain and a hard protrusion at stool, which was reduced by hand. External hæmorrhoids about the anus; the sphincter was hypertrophied and spasmodic. Large prolapsing hæmorrhoids in rectum; ulcerated; on the left side there was a small, hard mass above internal sphincter, very movable and easily dragged down outside the rectum. No induration at base

February 2d. Removed by clamp and cautery. Specimen sent to laboratory. Pathological report, melanosarcoma. February 25th. Parts entirely heaied; patient well.

February 25th. Parts entirely heaied; patient well. January, 1905. Patient continued to be in good condition. 1906. Lost sight of patient.

Case XLIX.—April 1, 1903. Mr. R. T. J., age sixty-five. Good color and well preserved. Had had heart trouble and morning diarrhea for a year and a half. Frequent, thin, watery stools with constant desire to defæcate. Anus normal. A small nodular mass, about the size of an English walnut, one and one half inches inside the rectum, attached to the posterior wall, movable and almost pedunculated.

April 7th. method. Ope Removed by modified Quenu (perineal) Operation very easy. Sutured the musculature of the rectum to the gut and the mucous membrane to the Removed two and three quarter inches. Pathological

report, adenocarcinoma.
April 10th. Mucous Mucous membrane sloughed, but deeper

April 20th. Parts granulating; sphincter regaining

May 12th. Parts healed; fair continence. 1908. Had no recurrence two years later. Had moved

and left no address.

CASE L .- April 7, 1903. Mr. A. E. G., age fifty-six. Family history was clear.

Ten years ago was operated upon for piles: six months later for carcinoma; Kraske.

Constipated; slight discharge of blood and mucus; no Anus normal except for cicatrix. A nodular hard growth surrounds the rectum for one and one half inches above the anus. Microscope showed same to be colloid carcinoma.

April 14th. Perineal operation. The growth involved the anal margin and extended two and one half inches up, also extended around the urethra, requiring excision of about three quarters of an inch of this organ; end to end about three quarters of an inter of this organ, the to che sturre of same. Dissection very difficult, owing to anomalous condition of parts, due to old operation. Little glandular involvement. Outer fibres of the external sphincter left and sutured around gut. Mucous membrane sutured to skin. Permanent catheter.

April 19th. Catheter removed yesterday; no leakage;

patient urinates with difficulty.

April 23d. Rectal wound practically healed; very small perineal fistula, with loss of a few drops of urine, developed; began passing sound.

May 10th. Patient went home, practically well; some incontinence. June 1, 1904. Patient still well; continence much improved.

February, 1908. Patient still well and attending to business.

CASE LI.-May 15, 1903.-Mr. H. H. W., age seventyeight.

Family and personal history clear.

Patient was a strong and well developed man. Constantly decreasing size of stool and increasing difficulty in defæcation for the past six months. Smarting pain in rectum; much flatulence. Anus normal externally, but just within the external sphincter was a lobular, soft, ulcerating growth, involving the entire circumference and extending three and one half inches up the gut. Pathological report, colloid cancer.

May 18th. Perineal excision; removed seven inches; sutured musculature to gut; mucous membrane to skin.

Peritonæum and dead space closed by sutures.

May 20th. Patient doing well.

June 21st. Patient left hospital; wound closed; partial incontinence.

October 17th. Recurrence, left anterior quadrant, one and one half inches.

December 1st. Recurrence in liver. Patient died about two months later.

CASE LII.-November 7, 1898. Mrs. L. B. A., age thirty-

Family history negative.

Patient had always been constipated until one year ago, when she began to have griping and alternating diarrhœa; frequent stools with loss of blood and mucus. Loss of flesh. Anus normal. Mucous membrane smooth in the rectum up to three inches, where was felt a large cauliflower growth, entirely surrounding the rectum and firmly attached to the sacrum. Section removed. Pathological report, adenocarcinoma.

November 12th. Bone flap operation. Removed six inches of the bowel; tied only four vessels; some difficulty in loosening the bowel from the sacrum, but bone did not seem to be involved. Vagina was cut into and sutured; peritonæum sutured; end to end suture of gut.

November 20th. Patient progressed well. Bowels moved

yesterday, and to-day there was a slight fistulous opening into the posterior wound.

November 30th. Attempted to sew up fistula; rest of the wound healthy.

December 7th. Stitches gave way; still leaking. December 15th. Patient left the hospital, well but for

March 1, 1899. Patient felt well and had gained in flesh. Fistula closed

October 15, 1899. Recurrence in situ and in liver. Patient died about four months later, chiefly from liver

symptoms. Suffered very little pain.

CASE LIII .- October 28, 1903. Mrs. H. I., age forty-five. History of cancer in family.

Personal history clear. Increasing constipation for years.
Headache and backache, worse at night. Dragging across the lower portion of the abdomen. Discharged a great deal of gas. Constipation relieved by enemas, catharties produce a diarrhea. Small external hemorrhoids about the

anus, otherwise normal. Small nodular mass in the left posterior quadrant of the rectum, three quarter inch above the anus.

ne anus. Movable, not painful; no glands enlarged. November 3d. Split rectum open posteriorly, excised the growth, and sutured the parts together, leaving postrectal wound open for drainage. Pathological report, adenocar-

November 15th. Small postrectal sinus, but does not enter rectum. Patient leaves hospital for home.

Doctor reported no recurrence three years later.

CASE LIV.—September 3, 1903. Mr. O. S. R., age forty-

Family history negative.

Hard drinker. Always constipated. About one year ago had griping, flatulence, and loss of appetite, followed by alternating diarrhea and constipation. Now passes mucus tinged with blood. Ten to fifteen stools a day. Anus normal. Rectum normal up to rectosigmoidal juncture. Proctoscope showed granular ulcerating mass, occluding the calibre at this point. Tumor could be felt through the abdominal wall when lifted up with the tube.

September 21st. Abdominal resection; eight inches re-

moved; colorectostomy. Liver hard, but not nodular.

Pathological report, adenocarcinoma.
September 25th. Nothing unusual; bowels moved on the second day; guy strings still hanging.

September 30th. Guy strings all away. Surgically the patient is doing well, but does not gain strength.

October 15th. Doing better; wound healed; opening at

junction of rectum and sigmoid ample.

November 26th. Patient gained strength and some weight, but color is not good. Left to-day for Canada.

March 5, 1904. Recurrence in liver; gradually losing. Patient died July, 1904, nine months after operation. CASE LV .- May 8, 1903. Mr. H. F. R., age fifty-four.

Family history clear.
Pneumonia once. Social drinker. Three years ago began to have pain in the left side. Ischiorectal abscess about six months ago. Was operated upon for hæmorrhoids about a year ago; successful. Constipated for years; slight discharge of blood and mucus at stool. Anus normal. tum normal up to the junction with sigmoid; here the folds were thickened and duplicated. Stricture eight inches from the anus; the proctoscope would not pass; unable to inflate by artificial or atmospheric pressure, bowels forced air out along tube. Hard, sausagelike mass in the left iliac fossa.

May 12th. Operation. Abdominal resection. Malignant stricture (scirrhus), involving the lower loop of the sigmoid, three and one half inches in extent. Removed six

inches; end to end suture; no drainage

September 20th. Convalescence uneventful. December, 1907. Patient well.

CASE LVI.—December 14, 1903. J. P. W., age fifty.

Family and personal history clear.

Seven years ago had nervous prostration. Numb pain in the lower part of back for a year or more. Six months ago had difficulty in having stool; much pain; could feel a tumor in the rectum with his finger. Had bleeding then, but not since. Alternate diarrhœa and constipation; discharged mucus at stool. Anus normal. A hard, nodular mass could be felt, movable, three inches up the rectum, and extending two and one half inches upward; top could be reached by dragging the mass down. Index finger fitted tight in calibre.

December 16th. Perineal operation; removed nine and one half inches; comparatively little hæmorrhage; sphincter preserved. Pathologist's report, adenocarcinoma.

January 2, 1904. Patient left hospital. Posterior fistula still

discharging.

February 10th. Rectum well; patient at work; some cystitis.

June 30, 1905. Recurrence in prostate, and small nodules in gut; removed, but found bladder wall involved. Parts healed, but cystic symptoms continued. Bright's disease developed.

Patient died December 1, 1905, two years after the first operation. Comparatively comfortable, and able to work

CASE LVII.-January 10, 1904. Mr. A. L., age forty-two.

Family history, clear. One year are began to have griping cramps, relieved by cold water injections; a feeling of unfinished business after

stool; cramps in the transverse colon. No pain in the stoot, clamps in the tansverse cools. No pain in recetum; recently some discomfort in the sacral region. Anus normal. A small, hard, nodular plaque was felt in the anterior wall of the rectum, three inches up; movable; nothing visible higher up; no glands enlarged. Pathological report, adenocarcinoma.

January 25th. Perineal extirpation, whole circumference removed; no complications. Convalescence uneventful. Continence restored.

December 15, 1905. Patient reported himself well.

No news later.

CASE LVIII.-November 18, 1903. Mr. M. O., age sixty-

Family and personal history, negative.

Constipated for years. Began to go to stool without adequate results a year ago. Blood first passed six or seven months ago. Flatulence and loss of appetite. Urgent morning stool, followed by ten or twelve movements a day, with blood and mucus. Pain in the sacrum, not acute. Anus normal. A large, friable nodular mass, three and one half inches up the rectum, extending beyond the reach of the finger, but movable. Pathological report, adenocarcinoma.

November 24th. Bone flap amputation; nine inches resected: anus denuded, and gut invaginated and sutured to the mucocutaneous margin. Guy strings through the meso-rectum and edge of the wound. Posterior drainage. rectum and edge of the wound.

November 30th. Patient did well until to-day, when he had a chill, and sepsis seemed to be developing; the wound and peritonæum seemed to be in good condition.

December 1st. Patient had double pneumonia; temperature, 104° F.; respiration, 42.

December 2d. No improvement.

December 4th. Patient died; wound in good condition.

Case LIX.—June 20, 1904. Miss M. J., age twenty-two. Patient was first seen in March, 1904; operation advised, but refused. Returned on June 13th; operated upon on June 21st. History unobtainable, as the patient spoke only Syrian, which we could not understand. Had diarrhoea, loss of blood and mucus from rectum; extreme pallor. Anus normal. Large cauliflowerlike tumor, friable, at about one and one half inches from the margin of the anus; freely movable; calibre barely admitted index finger; the growth extended about two inches upward into the rectum.

June 21st. Excised tumor by perineal method. Removed six and one half inches. Musculature sutured to bowel, mucous membrane to skin; no drainage whatever introduced

July 22d. Patient left the hospital perfectly well. Good continence. She never returned for examination; we were able to trace her for one year, the report being that she was perfectly well. Since this time no information has been received.

CASE LX.-February 18, 1904. Mrs. R. P. A., age thirty-

Began to menstruate at twelve. Born constipated, and had suffered from prolapse; pain on defæcation. Imperative demand for stool followed operation for stricture and hæmorrhoids. Considerable discharge of mucus. Right kidney movable. The anus was relaxed and moist. The rectum was irregularly narrow for five inches up, apparently congenital, but nodular. Sphincter hardly ap-

February 23d. Operation performed. Vaginal excision: posterior drainage; gut easily brought down; seven inches amputated. Circulation good. Sutured musculature to gut, and mucous membrane to skin.

March 1st. Primary union; functions good. Patholo-

gist's report, incipient carcinoma. January 5, 1005. Slight constriction at anus, otherwise

perfect.

March 29, 1908. Still well.

CASE LXI.-June 28, 1904. Mr. A. I. C., age sixty.

Family history, clear.

Four years ago had diarrhoea and passage of blood; blood less now than two or three years ago. Imperative diarrhea, three to ten stools per day, with blood and mucus; no discharge except at stool. Anus normal. The rectum is bright red, creded, and congested throughout Marked papilloma at the junction of the sigmoid; stricture at this point, but it does not feel hard or fibrous. There

was a cracked, irritated, bleeding appearance to the mucous

membrane above and below the papilloma.

June 30th. Removed papilloma with alligator and specimen forceps; no anæsthetic; cauterized with an electric cautery through an operating speculum, No. 1. No hæmorrhage, but packed. Pathological report, adenocarcinoma.

July 10th. Diarrhea had ceased; was able to pass proctoscope through the stricture to-day

April 5, 1908. Patient continued well.

Case LXII May 27, 1904 Mrs. S. W. C., age thirty-

Family history, negative.

Patient had always been constipated. A year ago she began to have increasing frequency of desire to stool; pain at the end of spine on defæcation. Bowels moved from ten to fifteen times a day; normal solidity after morning stool of blood and mucus. Smarting and aching pain in the rectum after stool. Anus normal; sphincter tight. Just within the anus a hard, ulcerating, nodular mass, extending all around the rectum, and two and one half inches up; calibre not materially lessened. Bled easily on touch; no glands to be felt.

June 9th. Perineal operation. Very difficult; broke

through into gut in dissection. Great prostration.

June 10th. Had suffered greatly from shock. Had in-

fection about wound.

June 20th. During my absence two abscesses broke, and there were now two cavities, anterior and posterior, discharging freely. Am afraid to lay them open lest the gut be loosened from its attachments. Patient gaining.

October 1st. Patient was kept under care all summer;

finally laid abscesses open, and they are now healed. March 17, 1905. Small nodular recurrence in margin; removed.

January 19, 1906. Recurrence in situ; removed two and

one half inches

November 5th. Marked recurrence. Colostomy done after finding prevertebral glands enlarged, and involvement of the liver.

May, 1907. Died, three years after operation.

CASE LXIII.-July 8, 1904. Mr. S. J. H., age forty-two.

Family history, negative

Personal history, negative. Always constipated. Three months ago had a feeling of bearing down, except when sitting or lying; desire to go to stool on rising in the morning. Flatulence and indigestion; stools are now thin and bloody, with occasionally a discharge of mucus. A hard, lumpy protrusion at stool, reduced by hand. Gedematous skin tabs about the anus. The rectum was filled by a large, hard, nodular, cauliflowerlike growth, beginning one half inch above the external sphincter, and extending three and one half inches up. Admitted the first finger.

July 15th. Operation. Perineal method; removed five inches; apparently a most complete operation. Gut easily brought down and sutured to the anal margin. External sphincter preserved. Pathological report, adenocarcinoma,

malignant type

July 20th. Union primary; not a complication, July 28th. Patient well; went home to-day.

December 3d. Recurrence in margin and in posterior glands, one inch above anus. Removed under cocaine: severe hæmorrhage from superior artery in removing the glands, controlled by leaving clamp on.

February 1, 1905. Recovered and feeling very well, except for cystitis; going South for recreation.

August 20th. "Liver trouble" developed in June, and

patient died August 12th.

CASE LXIV.-July 15, 1004 Mr. T. M. R., age forty

Suffered from pain and bleeding for one year: had an operation for harvorrhoids eleven months ago; bleeding stopped, pain never entirely relieved; soreness increasing normal. There was a hard, nodular mass one and one half inches above the anus in the posterior wall. Movable, no constriction. Adenocarcinoma.

Operated, perineal method; removed four July 20th.

and one half inches

August 30th. Convalescence uninterrupted. January, 1907. Patient well.

1908. Loss sight of, supposedly well.

CASE LXV.-August 29, 1904. Mr. T. D. J., age sixtythree

Always rugged and healthy; had syphilis forty years ago. Began to lose flesh in 1900, when in the Spanish-American war. Frequent and small stools, occasionally streaked with blood, no mucus; bad odor; morning diarrhœa. Anus normal. In the rectum, three and one half inches up, was a large, nodular mass, slightly movable; calibre almost obliterated, felt by upward pressure and deep palpation of the abdomen.

September 9th. Bone flap operation; removed seven and one half inches. Resection; end to end suture. Seminal vesicles removed; peritoneal cavity opened and sutured. October 1st. Left hospital well, except for a small pos-

terior fistula.

January 1, 1906. Reported well.

March, 1908. Died in March, 1907, recurrence in bladder.

CASE LXVI.—September 2, 1904. Mrs. E. L., age fifty. Family and personal history, negative.

Nine months ago began to have a nagging desire to go to stool. Losing in weight. Formerly constipated, now has morning diarrhea; discharge of blood and mucus at stool. Anus practically normal; sphincter relaxed. Two mehes within the rectum was a hard, nodular, sloughing tumor, barely admitting the finger, but was easily dilated; extended three inches up, and have very recepble.

extended three inches up, and was very movable.
September 12th. Bone flap operation. No complications. Anus denuded, and upper end of gut invaginated; musculature sutured around the gut; mucous membrane sutured to the skin. Pathological report, adenocarcinoma.

October 12th. Patient sent home, apparently well. June, 1905. Recurrence in situ and in liver; no further report.

CASE LXVII - September 6, 1004. Mrs A N, age thirty-four.

Family and personal history, negative.

Indefinable sensation in rectum. Sometimes dull, aching pain. Formerly constipated, but bowels now move four or five times a day, with urgent morning stool, discharge of nucus, tinged with blood. Anus normal. A small nodu-lar growth in the posterior wall of the rectum, movable, and producing no constriction, one and one half inches up, extended about one inch.

September 12th. Operated. Perineal method. Removed four and one half inches.

October 1st. Patient left the hospital to-day. Posterior fistula persisted, otherwise well.

January 26, 1905. Patient returned for an examination, feeling fairly well, but fistula had never healed. There seemed to be some induration at its upper end, but it felt more cicatricial than neoplastic. Advised irrigation.

September, 1906. Recurrence in liver. Patient died about eighteen months after the operation. CASE LXVIII.—October 7, 1904. Mr. N. W., age sixty. Tuberculosis in father.

Three years ago fistula developed. Operated upon ten months ago. Discharge from rectum and difficulty in retention continued. Bowels were regular, and there was very little pain. A protruding cauliflowerlike growth extended up the rectum five and one half inches. Lymphatics not

October 12th. Combined operation, making inguinal colostomy. Removed ten inches of the lower end of the rectum through the perineal floor; introduced drainage

October 17th. Patient did well until to-night, when he was found in a collapse, and died three hours later. Autopsy revealed no cause for his death unless coronary embolism. Pulse 72 and temperature 98.8° F. one hour before collapse.

CASE LXIX.-November 25, 1904. Miss L. S., age thirty-eight.

Father had indistinct history of neoplasm of rectum. Old history of retroversion and use of pessary. Operated

for fissure and hamorrhoids nine months ago; no relief. Irregular diarrhea; discharge of blood and pus. Internal blind fistula with pocket at anterior quadrant of anus. Sphineter normal. Rectum empty, catarrhal; small, broad based tumor, four and one half inches above the anus, on the anterior wall.

November 20th. Excised tumor and cauterized base with

an electrocautery. Incised fistula. Pathological report, adenocarcinoma

September, 1906. Very small growth, three and one half

inches in, similar to the first; removed in the same way.

March 30, 1908. No recurrence, patient perfectly well.

CASE LXX.—January 2, 1905. Mr. J. D., age twenty-

Family history, clear.

Personal history, doubtful venereal. Lost twenty pounds in six months, began in hot weather; previously constipated. Now has constant desire to go to stool. No pain; iregular diarrhœa; discharge of "slime." Anus normal. Rectum catarrhal. Hard, nodular mass three and one half inches up, barely admitted the finger; very slightly movable; extended five and one half inches.

January 8th. Bone flap operation; very difficult and prolonged; removed many glands, difficult to detach from the bladder. Brought the gut down and sutured to anus, Hoch-

enegg's method.

January 10th. Patient reacting well. Temperature, 101° F.; pulse, 110.

January 15th. Patient continued to do well; bowels had not moved; there was considerable suppuration from posterior wound.

January 20th. Bowels moved; some leakage. February 1st. Patient up and about; fistulous tract dis-

charging freely, and faceal discharge through it.

April 10th. Patient well except for slight posterior fistula, which is growing smaller all the time.

Patient reported well eighteen months later. Left the city, and address unknown.

CASE LXXI.-April 14, 1905. Mrs. A. T. F., age fifty-

Patient had had a tuberculous fistula for thirty years, but process in abeyance. In January, 1902, had a severe hæmorrhage from the rectum, followed by a nagging diarrhoa, and a smaller hæmorrhage six months ago, since which time she suffered from more or less bleeding and purulent discharge from the rectum. Recurrent headaches; rectovaginal fistula established three or four months since. Bowels moved frequently; cutting pain after bowels move, preceded by blood and mucus. Carcinoma occluding the anus, opening into the vagina; tuberculous fistula on left Carcinoma involved the rectum two and one half inches and the vaginal wall.

April 15th. Scraped out and cauterized. October 1st. Patient had used radium pencil all summer. Tumor remained about the same in density, but there was no extension or increase since it was cauterized. The fistula, the inner opening of which was burned out, had entirely healed.

December, 1907. Patient died from general peritoneal

and liver involvement; great suffering.

CASE LXXII.—April 30, 1905. Mrs. A. P., age fifty-

Family history negative.

Patient had been operated upon four years ago for rectal abscess. For the past four months she had noticed an enlargement in the left groin; severe pain in the abdomen; stools had been painful; always constipated. Anus very contracted, hard, and indurated; finger could hardly be introduced into the rectum, which was filled with a large carcinomatous mass, friable and nodular, and extending two

May 6th. Operated. Perineal excision of growth: five inches removed; gut brought down and sutured; inguinal

glands removed on both sides

May 10th. Rectal wound healing very nicely; some of the sutures in the mucous membrane had cut through, however. Pathological report, adenocarcinoma. May 15th. Dressing removed. Inguinal wounds healed

by primary union; rectum healing, but some granulation

around the anterior margin

May 25th. Patient left the hospital; some granulation around the margin of the wound. Never returned; no doubt, however, she had a recurrence.

Case LXXIII.—May 6, 1905. Mr. D. G., age forty-one. Always constipated; began to lose blood a year ago; frequent desire to go to stool, but without effect; very little pain and no discharge except when bowels moved. Anus normal. In the rectum, four inches above the anus, was a large, movable cancer. Calibre admitted index finger.

May 10th. Bone flap operation. Strong idnesions of the tumor to the sacrum and the prostate. Resected seven inches of the bowel; considerable hæmorrhage.

May 20th. Patient did well until to-day, when he had a large secondary hæmorrhage and died. Autopsy showed slough in the side of internal pudic artery, probably due to too tight packing.

(To be concluded.)

PSYCHOTHERAPY.*

BY ANNA M. STUART, M. D., Elmira, N. Y.

Whether the title of this paper will awaken any interest among a body of physicians or not, is uncertain, but if the same subject is discussed in a lay company, the interest is intense, and every one is agog like the ancient Gallilæans, for signs and wonders.

The religion of Mrs. Eddy has cut a swath through the world like that of Mahomet; Mahomet promised his followers a sensual paradise in the next life, but Mrs. Eddy promises hers one in thisbodily comfort and riches, and freedom from all responsibility for the sick, the poor, or the sinful. No wonder she makes proselytes by the thousand. More than this, in spite of her absurdities, her dynamic character has set in motion a hundred kindred movements that strive to be more rational, and yet follow along the same path. Nothing is more firmly fixed in the minds of the laity than their belief that psychotherapy is to be the coming wonder, that it is now only in its infancy, like ærial navigation and wireless telegraphy.

That such a power exists is true beyond dis-cussion, but that it is an infant with a great future is a matter for grave doubt. My belief is that they have not an infant but a changeling in the cradle—a little old dwarf, old as the Middle Ages, old as Homer, old as Egypt, old as Job, and the Chaldean pasture lands. He has been well tried. We know all about him, his power and his limitations.

Every skillful physician is a mind healer, if he is not that, he does not succeed no matter how great his knowledge of disease. He considers the mind of his patient in everything he says and does, in his choice of attendants, and in his instructions to the family. Every word spoken in the sick room is as carefully weighed as the medicines, and he will at once discharge a nurse whose mental atmosphere is not healing to the patient. He seldom tells the names of his medicines because his best remedy will play him false if the patient has a groundless prejudice against it.

The physician may be ill himself or in grief; you may wound him, anger him, or even discharge him. but he will bear everything with a placid smile in the sick room. He has built a wall of tranquillity. courage, and hope, about his patient, and he will never break it down. He knows that he must make frequent calls in self limited diseases, also even in hopeless diseases, because the steadying presence of the one who knows will bear the ship better through the storm, or quietly down to its last port. This is the art of medicine, not taught in our schools,

[&]quot;Read before the Chemung County Medical Society.

but handed down from man to man—the mantle of Hippocrates.

Now the science of medicine is a very different old lady. She is suspicious of everything which borders on the mysterious and occult. She does not wish to investigate anything which is im-She classes all inexplicable phenommaterial. ena together under the head of therapeutic suggestions, then draws her skirts carefully away. One cannot blame her. She has suffered much at the hands of sorcerers, magic mongers, and charlatans. She has been for centuries extricating herself from the superstitions of the Middle Ages. There was a time when her pathology was confounded with the movements of the stars. There was thought to be a vast image of each man called his archetype, projected on the highest heaven of the empyrean—the man's diseases were caused by the action of angels and demons, together with that of constellations and planets on the organs of this archetype. A survival of this teaching is still seen in the man on the front of the almanac. Her therapeutics has at last dropped out amulets, charms, relics of saints, pilgrimages, etc. She says, "I am an inductive reasoner-you can make no rule for me, and bring me no remedy that you cannot hand over to the staffs of a hundred great hospitals, and prove by volumes of statistics." Nevertheless, in her sadder moods she bewails her own inexactitude.

Astronomy has shaken off astrology forever, and walks hand in hand with mathematics; and her sister chemistry is freed from the old alchemy and steps accurately with numbers. But medicine, poor medicine, is always helped or thwarted, by an unknown quantity in all her calculations, the mind of man which cannot be taken out while his body is being mended. She gets a new fad or discovers a new remedy. Her professors rush after it, and the sick and crippled follow with a shout. But soon, some one's faith fails, and no more sick are healed after the troubling of the waters. Then we say to medicine, "How was it that the treatment you now disown, actually healed in the days of your enthusiasm?" and shamefacedly, the "old lady" confesses it was the same then as in the Middle Ages, mere therapeutic suggestion. The sacred Bambino, or the relics of St. Ursula, would have done as well.

The first to present mental healing, as such, to the scientific world, was Mesmer in the eighteenth century. He was inspired by the writings of Paracelsus. That brilliant but aborted genius thought he saw a great light in the idea of the unity of man with the universe, and was dazzled by the vision. The evolutionists have since shown to the smallest detail, this unity of man and the uinverse. But Paracelsus thought he had reached with a bound the source of all knowledge; the answer to the ancient Hindu question, "What is that, knowing which all things are known?" He wasted his energies and destroyed the value of his discoveries by disregarding the small, but still precious accumulation of scientific observation. He publicly burned the books of Galen. And at the last gave himself up to the study of mystic Hebrew writings called the Caballa. Mesmer evolved the theory of animal magnetism. He went to Paris and threw that city into wild excitement by his startling cures of dis-

ease. The medical men scoffed at him, but he believed in himself and asked for an investigation by the Academy; which was granted him. There was an American present as member of that commission, Benjamin Franklin, who was our minister to France. The commission admitted his facts but denied his theories, and two years afterward Mesmer was driven from Paris in disgrace. Not until Charcot made public his experiments in the Salpêtrière, was this strange power recognized by science under its new name, hypnotism. It is to the point here to quote the late writings of Charcot after all his experiments. He says the hypnotic state is accompanied with grave dangers to the subject, and should never be induced except under great necessity. Coming now to our present time, we find a host of eloquent lay writers spreading themselves gloriously in the train of Mis. Eddy's comet. The peo-ple call them all "new thought." There is even a journal by this name. There is nothing new however, in their philosophy, it is all borrowed from the modern German school of idealism, and that, in turn, is evolved from the neoplatonists, and can be traced back through Plotinus Porphysy and Plato. and one could still use as good textbooks the most ancient Hindu scriptures, the Bhagaradgita and the Upamshads. In fact there is a little gift book of extracts from the Upamshad, in fancy binding. All this, however, is in no way interesting to the physician. Quite in contrast, however, is the book of Paul Dubois, professor in the University of Bern, you have received an advertisement of last week, telling of the Emanuel Church movement and of their endorsement of this book. You must realize in reading that folder, that probably it has been sent, not only to every physician, but to every minister, in the United States, as well as to laymen, and when you read the book you must think of the effect upon all these many readers.

Dubois does not at all assert that he can cure physical disease by mental means. The originality of his work lies in his rather arbitrary classification of a number of neuroses as purely mental diseases, not dependent in any way upon any physical disease which may accompany them. He calls them psychoneuroses, and includes all kinds of nervousness from neurasthenia, hysteria, melancholia to degeneracy, digestive troubles, emotional diarrhœa, habitual constipation, polyuria, insomnia. The insanities are a step further, and he does not touch them. He mercilessly scores physicians for treating these cases on a physical basis, making analysis of the stomach, repairing uterine tears, etc. He firmly, pleasantly, and persuasively explains to these patients that they are not sick people, but fools, that they must take themselves in hand and reform. He speaks constantly of the necessity of being patient and persuasive. He has an eye for just one thing—a neurosis. He admits that even if he discovers tuberculosis, he ignores it, because otherwise he would weaken his power of cheerful suggestion. See what it is to be a specialist. He cures his specialty, and takes no further responsibility. He objects to methods of exact diagnosis, on the ground of their increasing the fixed ideas of the patients. He admits the necessity of surgery for appendicitis, and similarly serious troubles, but he scoffs at medication,

calling it a bungling form of suggestion, practised because the public has been trained to it. He says "we are like the Roman augurs, who could not

think of themselves without laughing.

Imagine the effect of all this on the minds of the public already bitten with the superstitions of wonder working. When we begin to laugh at ourselves, to throw stones at our own art, we deserve the sneers we receive. Whoever is so discouraged, lazy, or cynical as to lose his faith in his therapeutics, let him read the ringing article of Jacobi in the New York State Journal against Therapeutical Nihilism. Read it over twice and highly resolve that none shall die because of his slackness. The public —alas, the dear public, as many a disappointed man has called it-makes no nice distinctions; all medicines will cure or none; if any diseases yield to mental treatment, why not all. The public is a deductive reasoner. "Why," it says, "if," then "so and so, that is reasonable"; forgetting there may be a flaw in the premises. The public is being rapidly educated—flying machines and wonderworking—no more tedious methods—just as scientific medicine is emerging with real trophies-diphtheria, typhoid fever, tuberculosis, malaria, all in hand to be wiped out for the near future generations. Think of a happy world in which the young do not die. Then, too, the solution of cancer may not be far off. For all this, we need the cooperation of society—only a society that believes in germs and disease, will buy watersheds, will police milk districts, drain marshes. segregate tuberculosis patients, build model tenements, stop the traffic in child labor, pay for cancer laboratories.

Just as we are on the eve of these great victories this cloud appears on the horizon, this wave of superstition from the Middle Ages, that will blot out our advance as the ashes blotted out Pompeii.

You think I am extreme; just wait ten years until this leaven has leavened the mass of public sentiment, you will see a great falling off in the endowments to hospitals, medical schools, and laboratories. People have always grudged their pity, and will soon have a good excuse for withholding it. Hear what the English divine, Mr. Chesterton, says of Christian Science. I quote it here because it applies equally well to the popular idea of the new thought and therapeutic suggestion. "I say Christian science is a mean and disgusting philosophy, preached by people who are quite nice-preached, in fact, by my personal friends. They are all right,it is only their creed that comes from hell. I use the phrase quite calmly and quite literally. The doctrine that pain and death are not real at all except in so far as their victims are cowardly enough to submit to them is a diabolical doctrine, obviously calculated to produce all the purely diabolical qualities, such as intellectual cruelty and contempt for the weak. . . Ever since the crucifixion a certain actuality, and therefore a certain sanctity, has clung around the hard pain of prosaic men. Men in misery were sometimes dismissed as nuisances who could not be cured, but they were never despised as cowards who ought to have cured themselves.

If a minister was really anxious to ameliorate the suffering of humanity, I could educate him in a week I should like him to spend that week in a large children's hospital and live among the little crippled bodies and wizened vellow faces of those innocents slain from their birth, who shall never come out of tribulation, for they are destined to bear the burden of all the sins and ignorance and greed of our society. There let the minister ask and answer his questions as to the actuality of disease.

Did any of you, you who have walked these hospitals, ever try to sleep with a limb in a plaster cast? If you had my experience you did not sleep, but you saw visions; visions of long vistas, interminable vistas of little white beds, with little bodies stretched on hard boards, and little old patient faces, and thin white fingers. You felt ashamed to groan, but you seemed to hear a bell intoning, not for those who go down to the sea in ships, but for all little children sleeping in plaster this night, in all the hospitals in

all our great cities.

Let the minister remain a week, and I trust he will not come out ready to amuse himself or his surfeited parishioners with experiments on neurotics, but he will manfully put on the cloak of his own calling and from his vantage of the pulpit thunder against the wrongs of the world. He will have sermons for a hundred years and he will never have to change his text—"In Rama there is a voice heard, Rachel weeping for her children.'

656 PARK PLACE.

A CASE OF TUBERCULOUS PERICARDITIS; EMBOLIC HEMIPLEGIA THREE DAYS AFTER PARACENTESIS OF THE PERICARDIUM.*

BY MORRIS MANGES, M. D., New York, Visiting Physician, Mount Smar Hospital.

The patient, Michael P., aged nineteen, occupation porter, was admitted to my service at Mt. Sinai Hospital on September 6, 1907, after five days illness of sudden onset. He complained of fever, pains in the head, chest, and epigastrium, and a cough. On admission his fever was 104° F. respiration 32, pulse 120. The examination was absolutely negative except for a few moist râles in the chest and a marked enlargement and tenderness of the liver, the latter reaching four fingers below the free border. The heart was absolutely normal. Leucocytosis was 13,000; urine negative; Widal negative.

For ten days the patient's condition remained practically the same, the main complaint being referred to the region of the liver. There was marked rigidity over it; there was considerable abdominal distension. The fever was high, moderately remitting temperature; respirations kept between 32 and 36; leucocytosis ranged between 14,000 and 25,000. He also had a vague macular rash resembling a roseola. No positive diagnosis could be made

September 16th: Cyanosis was noted, and it was found that the heart area had increased moderately to the right;

but there was no evidence of pericarditis or endocarditis. September 24th: During the past week the condition remained as before, with the exception that the liver was now beginning to diminish in size and was less tender. was less cyanosis. There were many râles at the right base. The leucocytosis was down to 10,000. The heart area was somewhat larger, especially to the right; no murmurs or pericardial signs; the apex beat was distinctly felt.

October 2d: Besides having had sharp, sticking pains in the left hypochondrium for a few days it was noted that the cyanosis was more marked. For the first time distinct signs of paricardial effusion of moderate size could be made out. The apex beat could not be felt. For the borders of the heart, see diagram. Paradoxical pulse was felt for the

^{&#}x27;Read at the twenty lifth annual meeting of the American Clima tological Visconation, at Boston, June 9 and in, 1998.

Blood pressure was 110 (systolic). Leucocyfirst time. tosis 6,600.

October 4th: The amount of pericardial effusion increasing (see diagram). The general condition was better; no dyspnœa (respiration for the past two weeks being 24).

October 9th: General condition practically the same, but signs of effusion were increasing; apex beat could be felt in the fourth space, ten centimetres from the middle line. There was marked change in pericardial dullness on change of position; dullness at the base of the left lung with a few râles. Liver still enlarged four fingers, but not tender; spleen palpable two fingers below free border. There was an irregular, moderately remitting fever; pulse irregular

and 80, paradoxical; respiration 24.

October 11th: A sudden and severe attack of dyspnœa during the night rendered aspiration advisable for the first time. A fine aspirating needle was introduced to the fourth space, five and a half centimetres to the right of the middle line; ten cubic centimetres of serosanguineous fluid were withdrawn. The needle was again introduced into the left fifth intercostal space, thirteen centimetres to the left of the middle line in an upward and inward direction for about four centimetres; ten cubic centimetres of similar fluid were obtained. This needle was then withdrawn and a trocar and cannula were inserted in the same spot and in the same direction, and connected with a Kroenig aspirating same direction, and connected with a Kroenig aspirating siphon and 600 c.c of serosanguineous fluid were withdrawn. Great relief was afforded by this, the pain in the liver and the dyspnœa ceasing almost immediately. It was to be noted that the paradoxical pulse disappeared after 100 c.c. had been withdrawn. No pericardial friction rub was heard after the withdrawal of the fluid.

October 14th: Although the fluid had reaccumulated moderately, the patient's general condition continued to improve very much. In the afternoon while eating the patient was suddenly attacked with a complete right hemiplegia; no con-

suddenly attacked with a complete right learning as a vulsion or loss of consciousness.

October 17th: General condition fair; the right facial paralysis was disappearing, but the paralysis of the right extremities continued unchanged.

October 28th: Involuntary defæcation and urination; patient more apathetic; cyanosis and dyspnæa increasing. pericardial effusion was increasing so that he was again aspirated, this time by Dr. Albert Kohn, in the fifth space eleven centimetres to the left of the middle line, but nothing was obtained. The needle was then inserted in the fourth space, six and one half centimetres to the right of the mid-dle line and three cubic centimetres of clear strawcolored fluid were obtained. As the patient's condition became bad, no further attempts were made to withdraw any more fluid. November 2d: Over the entire back of the nape of the

neck to the sacrum is a large area of even, dark brownish pigmentation. Fluid in right chest; no change in heart.

November 22d: The loss of power of the upper and lower extremities remained unchanged. The paralysis was a flaccid one. The deep reflexes are missing.

November 27th: The pericardial fluid having been reported to be tuberglous in critical fluid having been reported to be tuberglous in critical fluid having been reported to be tuberglous in critical fluid having been resident.

november 27th: The pericardial hind naving been reported to be tuberculous in origin, von Pirquet's reaction was tried with a slight positive result.

December 7th: Heart unchanged; the patient's general condition was better. There had been very little fever for the past month. Pulse and respiration normal. In the af-

ternoon the patient had an epileptiform convulsion involving the left half of the body, lasting thirty seconds.

December 13th: Patient still had a complete right hemiplegia with slight evidences of right facial paralysis. Reflexes on the right side were absent in the upper and lower extremities and also on the left side, the condition of paralysis being flaccid rather than spastic. Patient had similar convulsions of a somewhat more severe type on December 17th, 25th, and January 4th and 6th. A small amount of fluid was noted in both chests on December 21st.

January 6th: Had hallucinations and delusions, this mental confusion lasting for two days.

January 15th: The heart area unchanged; but the fluid in

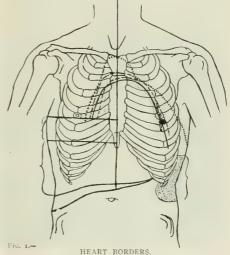

January 15th: The heart area dischanged, out the hind in the left chest increased and was there aspirated.

January 17th: Pericardial shuffle was to be heard in the third and fourth spaces to the right and over the lower sternum. This persisted for the remainder of the month.

The patient's general condition was practically the same until April 15th, when the dyspnœa and cyanosis suddenly increased. There was dysphagia; the heart borders again began to move out; leucocytes were 15,000, polynuclears ninety-one per cent. The temperature rose, the pulse became very irregular, and the patient died suddenly on the 20th of April, 1908, with increasing cyanosis and dyspnæa.
Autopsy performed by Dr. B. B. Crohn, April 21, 1908:
General: Rigor mortis marked except in right upper and

lower extremities (this side had been paralyzed). The circumference of the left thigh at its middle was 27.5 cm., the right thigh is 30 cm. Typical brownish pigmentation present over the body, not marked on hands and forearms, feet, or legs.

teet, or legs.
Thymus: Only remnants present. Diaphragm on the right and left side in the fifth space.
Lungs: Right, densely adherent; congested. Full of miliary tubercles. Bronchial nodes enlarged and pigmented. Left, very densely adherent. Changes the same as in right lung. Rather old, reddish thrombus was found in one of the medium sized pulmonary veins, the area drained by which looked somewhat like infarcted lung. Between the lower lobe and the diaphragm there was a large, sacculated collection of clear fluid. The wall was made up of thick, dense mass of fibrous tissue lined on the inner side by fibrin. The wall did not present any features that were typically tuberculous. Heart: Pericardium contained 300 c.c. of straw colored,

September 17 —.... September 12, 16, 24 = --October 1, 2 = ---October 9

— apex beat 10 cm. from median line.

clear fluid. This fluid was mostly to the left of the heart. The entire paricardial sac was converted into a thick mass of recent and old fibrous tissue varying from 0.5 to 1.5 cm. in thickness, lined on the inner side by a layer apparently in thickness, lined on the inner side by a layer apparently of fibrin of different thickness in different parts. No distinct tuberculous lesions were present. (Fluid from the pericardium had been inoculated into a guinea pig during life and tuberculosis proved.) In the mediastinum, just above the pericardial sac to the left, there was found adherent to the pericardial sac a lymph node about the size of a bean, which showed marked cheesy tuberculosis. Vena cava superior was somewhat constricted where it emerged from the pericardium. Inferior vena cava negative. Both auricles of the heart were dilated. The muscle of the heart looked cloudy. There was some old thickening of the mitral and aortic valves (at their insertion) and slight thickening of the tricuspid valve. The aorta and coronaries

Abdomen: Between 50 and 75 c.c. of clear fluid present.
Spleen: About three times the normal size. On section pulp dark in color, very easily scraped off.
Liver: Very much enlarged, fatty.

Kidney: Capsule somewhat adherent. Few cysts on surface. On section firm, congested, looked somewhat fatty.

Mesenteric and lymph nodes: No evident tuberculosis.

In the distal half of the transverse colon and descending colon there were some small, healing ulcers, apparently of tuberculous origin.

No important changes in the other viscera.

Brain: Dura, pia, and convolutions showed no abnormal-The putamen of the left lenticular nucleus was necrotic, with an area of yellow softening in its centre, about 12 mm. in diameter. The remainder of this part was in the stage of red softening. The branch of the middle cerebral supplying the putamen was not obliterated although smaller in calibre than that in the opposite hemisphere. The portion of the brain surrounding the putamen appeared to be unaffected.

Of this history of seven months' standing, many of the details have necessarily been omitted. Undoubtedly the most striking feature is the hemiplegia. Indeed, so far as a careful search of the literature shows, it is unique, for this complication has never been reported before in a case of peri-

paracentesis which was performed three days before the occurrence of the hemiplegia. Twelve hours after tapping or washing the pleural cavity was the longest interval noted in Leichtenstern's series. Still it is possible that the paracentesis and the removal of the fluid may have loosened a portion of the thrombus in the pulmonary vein when the lesser circulation was improved and rendered freer by the relief afforded by the removal of the fluid from the pericardial cavity. Then later on possibly some extra exertion while he was eating may have caused a bit of thrombus to be detached and thus cause cerebral embolism.

Mechanical causes, such as were supposed to explain the action of pleural effusion by Bartels, Rosenbach, and others (twisting of the heart, bending of the superior cava, etc.) cannot be invoked

i ray porture taken on October 9, 1967. The lower part of the plate was unfortunately damaged during the development, the marked enlargement of the cardiac area to the left and the right angle formed by the upper left border at the junction he great vessels. This shows very beautifully the "chimney pot shape" of pericardial effusions. with the great vessels.

cardial effusion. That it is possible is shown by the fact that a few cases have been reported as complicating pleural effusions both serous and purulent. Some of these pleural cases are directly connected with tapping or washing the pleural cavity, others may be explained as being metastatic pyæmic abscesses in the brain rather than being truly embolic in origin. Still there remains a small number of cases of hemiplegia (Cases XI, XII, XIII, XV, and XXI of Leichtenstern's series2) which occurred in patients with pleural effusions, but which were in no way associated with the mechanical emptying of the pleural cavity.

I believe the present case must be considered analogous to the last group, for it is hardly possible that the embolism was directly associated with the here since the heart cannot be displaced so much, and furthermore the only change found at the autopsy—the compressing band over the superior cava -merely contributed to the marked cyanosis.

That the hemiplegia was embolic is clearly proved by the condition of the blood vessels supplying the area of softening in the putamen, and by the fact that the brain and blood vessels are otherwise absolutely normal. Furthermore the source of the embolus was demonstrated in the thrombosis in the pulmonary vein.

Another feature which deserves mention is the fact that the hemiplegia was flaccid rather than spastic, that the reflexes disappeared, and that a partial reaction of degeneration developed. These are undoubted evidences of cord or peripheral disease. Unfortunately at the autopsy this point was left unsettled. Possibly the case might be included under the flaccid paralyses which are described by Bouchard as occurring in children, but this must remain a matter of conjecture on account of the

absence of anatomical data. Whether the psychic phenomena were due to the softening as were the epileptiform convulsions, or whether they were associated with the pericarditis as described by Da

Costa, must also remain doubtful.

As a case of tuberculous pericarditis its onset was most unusual: what were the exact relations of the early abdominal symptoms which were so markedly manifested in the enlargement and tenderness of the liver, were at no time explained, not even at the autopsy. How pronounced these symptoms were may be shown from the fact that for the first few weeks the case was regarded (so far as the diagnosis was possible) as some obscure form of disease of the liver, and it was not until the effusion had reached some size that the true nature of the condition became apparent. This obscurity was further increased by the fact that the effusion developed insidiously without any pericardial murmur. The enlargement of the heart was regarded as being a simple myocardial dilatation, for endocardial murmurs were also absent. It is also to be noted that it was not until very near the patient's death that any pericardial shuffle was heard and then in an atypical place, low down under the sternum and in the adjacent fourth and fifth spaces.

The tuberculous nature of the disease was not established by the cytology of the fluid nor by the finding of tubercle bacilli, but only as the result of inoculation of the fluid into a guinea pig.

It is also to be noted that neither hemiplegia nor pericarditis caused death, since this was due to mili-

ary tuberculosis.

It may seem strange that nothing further was done to treat the pericardial effusion. Further aspiration was deemed dangerous since it was feared that further embolism might be caused by aspiration. To attempt pericardial drainage by incision in this weak tuberculous hemiplegic seemed to be

a hazard which was unwarranted.

As regards the site for puncture, my experience in this case (see the diagram and x ray picture) and the findings at the autopsy confirm the statements of Curschmann, Shattuck, and Sears, that the best site is on the left side a short distance within the left lateral horder of the effusion. Here there is the least danger of injuring the heart. The specimen showed most beautifully that the major portion of the effusion lies to the left of the heart. It is needless to discuss this and other points on the topography of the effusion since this entire subject has been fully considered in Curschmann's monograph, pages 411-448.

Furthermore I would also corroborate Curschmann's preference for siphonage in tapping pericardial effusions, for my experience in paracentesis of the pleural and pericardial cavities favors the siphon rather than the aspirator, especially now that we have so simple and perfect an instrument as Kroenig's siphon bottle.6 Kroenig's needle I have discarded, since it is too large for ordinary use.

72 EAST SEVENTY-NINTH STREET.

SKIAGRAMS OF FOREIGN BODIES. DETAILS OF EXPERIMENTS.*

> By B. ALEXANDER, M. D., Budapest, Hungary.

Some time ago Dr. B. Alexander, of "plastic radiographic" fame, began a series of experiments with the object of demonstrating that simple skiagraphy alone offers a better means of distinguishing foreign bodies (as to position, situation, shape, distance, depth, etc.) than any other method now in vogue. Because of the importance of the subject and the great possibilities it involves, the instructive and interesting results of those experiments are worthy of being brought to the notice of the Amer-

ican medical profession.

There are various methods of locating foreign bodies, but each one of them, with possibly the exception of the stereoscopic method, is open to many errors, and on account of the complicated technique is not practical. The interpretations of Alexander's skiagrams, as shown in Figure 1 and Figure 2, marks a distinct advance in the scientific methods of localizing and distinguishing foreign bodies. By means of his skiagram Alexander proves that we may infer the distance of the foreign body from the plate or its exact position and situation within the tissues, and their relation to each other, if there be more than one; furthermore, his radiogram admits of an inference as to whether the foreign bodies are above or under the bone, and whether they are simply radiographed through the tissues or whether their image is projected upon the sensitive plate.

These skiagrams, Figs. 1 and 2, are those of a hand after amputation, containing various foreign bodies, as pins, needles, small shot, pieces of lead

from a pencil, etc.

The small shot marked No. 1 have been fastened to the skin of the wrist by means of rubber adhesive plaster, and marks the condyles of the scaphoid. Being outside of the skin, their picture is very distinct, uniform, and even the adhesive band can be distinguished as a white patch causing the uniform-

ity of the shot's picture (No. 1).

No. 2 marks shot fastened to the back of the hand; the picture appears to be more opaque and confluent in its shading; its dullness is more pronounced on account of the picture of the adhesive plaster together with that of the shot being projected through the soft tissues and bones upon the sensitive film of the plate. These two pictures offer interesting data for comprehending and correctly interpreting the rest of the pictures as to position and relation to each other.

No. 3 marks the shot near the basal phalanx of the little finger. This picture is very distinct and sharp, but is not uniform; with a little magnification we are able to distinguish a plasticity with all its shadings, as the attempt of reproducing the same in the sketch given later indicates. We see, besides the very sharp outlines, a narrow and bright zone which is unevenly shaded in its circular course, that is, darker at a point looking toward the epiphysis

^{*}Read before the Hungarian Surgical Association at Budapest. lune t, 1907, and published to the 172 Green Translated from the Hungarian, with permission of the author, by Dr. E. Rosenberg, of Cleveland, Ohio

of the basal phalanx and gradually fading as it approaches the metacarpal of the fourth finger, and thus, by the different gradations of this shading, a spherical form or bullet mold, i. e., the plastic picture, is formed, which is more conspicuous on the negatives than on the printed positive or printed copy of the latter. Accordingly we infer that of all the shot contained in the tissues the one under discussion (marked No. 3) is nearest to the plate (in the subcutaneous connective tissue of the palm).

and that the x rays were capable of producing its plastic image through the soft tissues. The rest of the shot pictures do not exhibit such plasticity nor any such striking brightness with the exception of possibly No. 4, proving that this shot is under the bone and has been radiographed through the soft tissues and bone. No. 5 is uniform and sharply outlined, being located in somewhat deeper soft tissues. No. 6 is beginning to lose its sharpness, indicating its still deeper location. In No. 7 there is still a

To a skineram of a left hand a few hours after amputation, with special reference to the foreign bodies.

pretty good brightness of the picture, though the sharp outlines are entirely gone, hinting that its location is still farther from the plate, in the neighborhood of the basal phalanx of the thumb, and covered by the thick antimanus, has been skiaand graphed through the bone. Nos. 8 and 9 are dull and indicate that they originate from a proportionately wide distance, that is, from the dorsal subcutaneous region. No. 10 is still duller, indicating that the shot is not only located very far from the plate-dorsal subcutaneous connective tissue -but is also projected through bone tissue. (Compare with Nos. 4, 5, and 8.) Nos. 11 and 12 will not be very hard to determine after what has been thus far demonstrated; the former one (No. 11) originates from the shot in the palm of the hand (under the hamatum), while the latter (No. 12) is in the dorsal connective tissue of the hand (behind the scaphoid), and accordingly No. 11 has been radiographed through soft and bony tissues, and its picture is therefore uniform and sharply outlined, while No. 12, being projected through soft and bony tissues, has therefore lost the sharp outlines, and appears to be faded and indistinct (distance and obstruction); the same relation is here shown as in shot marked Nos. 4 and 10. The

last shot picture, No. 13, will also be easily located; the sharp outlines are absent, it is a little dull, therefore is originating from the dorsal part of the phalanx and accordingly has been projected through the bone (compare with No. 4, which has been radiographed through the bone); its picture is somewhat brighter than Nos. 10 and 12, because the diameter of the phalanx is less than the one of the metacarpus or carpus.

With reference to the pictures of the needles, we will consider at first No. 14. We can read from this picture that the part corresponding to the eye of the needle lies farther than the point (the needle entered from the dorsal tissue of the little finger's basal phalanx and passed behind the fourth metacarpal head of the little finger into the volar tissues, but did not quite reach the subcutaneous palmar connective tissue). In accordance with its course through the tissues, we find the picture of the needle is most distinct at the point, the shadow of the needle gradually becoming more dull, until at the distal end (eye) it is entirely flat and indistinct.

Nos. 15 and 16 are the pictures of parts of one fine needle and do not seem to differ much; the thinner part, No. 15, is in the volar tissue just beside the end phalanx of the fourth finger, while the thicker part (No. 16) is close under the nail; it appears that the latter's picture is more distinct than the former one, but considering that this part of the needle, No. 16, is thicker, while the one lying more in a median line is thinner, we may infer that those needle parts are not in the same plane. Nos. 17 and 18 interestingly illustrate the relation of the needle's position. The needle part marked No. 17 is in the soft volar tissues, while the one marked No. 18, running obliquely over the os capitatum, is inserted into the dorsal tissues (compare with shot pictures). As to No. 17, we notice that its thicker end is more sharply outlined than its thinner end, which is more dull and faded, and accordingly the picture alone is explanatory of the relation as to position, i. e., the pointed end of the needle fragment lies deeper (farther from the plate) than its thicker end, which is in the subcutaneous adipose tissue. The pictures of the two pins crossing each other, Nos. 19 and 20, are still better illustrations of the relations as to position. No. 19 clearly indicates that the head of the pin is closest to the plate, and in proportion as the sharpness of the outlines are gradually diminishing, we may infer the distance from the plate is growing wider. Ouite the reverse is to be seen in No. 20; the pin enters the back of the hand and passes between two bones into the palm. The picture of the pin's head is dull and

indistinct, because it lies far from the plate, and is above the bones under the dorsal skin; while in proportion as the pin draws nearer to the tissues of the palm under the bone the picture grows more distinct, thus clearly indicating its course and position. The same relation is seen in Nos. 21 and 22. It is clearly seen that the brighter picture marked No. 21 is from the needle lying in the palmar tissues, while the duller picture (No. 22) answers to the needle imbedded in the dorsal tissues above the bone.

Fig. 2—Skiagram of a man's left hand, oblique and perpendice by a stadiation Primary and secondary pictures combined on one plate.

We also notice that the needle in No. 21 is not quite horizontal, i. e., its pointed end appears to lie deeper, being fainter, while its thick end is shown to be nearer the plate (more distinct).

More interesting data are offered by the pictures of different colored lead pencils, as seen in Nos. 23, 24, 25, and 26. The ingredients in the lead pencils are almost the same, only the pigment and the clay are different. The latter may account for getting different picture values.1 No. 23 is the picture of a piece of red lead pencil, the coloring matter is supposed to contain cinnabar, red sulphuret of mercury; its picture on the plate is very bright, clear, with sharp outlines; its uniform dark picture on the photographic print also shows sharp outlines, though it has been radiographed through the bone. Just as much obstruction as the red lead piece offers to the x rays as easily do the latter penetrate blue lead pencil. No. 24 demonstrates this fact, being the picture of a piece of blue lead. It appears as a very pale shadow on the print, its picture on the plate is dull and darkly shaded. Comparing No. 23 and No. 25 (both are pictures of red lead pieces), their pictures show which piece lies under (volar) and which one above the bone (dorsal); and accordingly No. 23 appears bright and sharply outlined, whereas No. 25 is dull and faded at the border, having been projected through the tissues. Nos. 24 and 26 are pictures of blue lead pieces, and we see the one, located in the volar tissues, as a pale shadow (24), while the other one, placed in the dorsal tissues of the hand, presents a still paler shadow than the bone picture next to it (26).

Nos. 27, 28, and 29 represent sesamoids in the sheaths of the tendons.

Considering that this skiagram of the hand (Fig. 1) had been made with the object of but illustrating the relations of the foreign bodies placed in the tissues of the hand, with reference to their location and to each other as well as to the behavior of the x rays in making radiograms of foreign bodies placed at different distances from the sensitive plate, we should not be surprised at seeing the incomplete radiogram of the hand itself, as to illustrating soft tissues or structural relations of the bones. On the other hand, if our aim has been to obtain a good print of the bones, then the pictures of the foreign bodies will not present so many and instructive illustrations, owing to the prolonged exposure required, thus sacrificing the fine and very important detailings of the foreign body. At the same time a study of Fig. 1 in many respects obviates the necessity of resorting to stereoscopic pictures, since in many places the relations as to distance are so striking and conspicuous that autosuggestion is entirely out of the question. Of course, the eye of the skiag-rapher or observer viewing the different relations on the negative must be trained for a long time before being enabled to correctly interpret such negatives.

To what an extent the skiagrams of the foreign bodies are changed if we aim at getting good bone pictures is shown in the following, Fig. 2, a skiagram of the same hand.

The skiagram as depicted in Fig. 2 differs from the former one (Fig. 1)in many ways. The hand is the same, the foreign bodies imbedded in it are, with slight omissions, the same; the outlines, the shading of the soft tissues, and even its details, are visible; the picture of the osseous structure is sharp and distinct, and yet this radiogram is not the simple result of a single skiagraphic examination, but is obtained by the use of one tube and exposing in two directions, and thus producing two shadows upon one plate projected upon each other. This experiment was made in the hope of obtaining additional data of information as to position, location of the foreign bodies; accordingly the hand was skiagraphed obliquely and perpendicularly. This procedure destroyed the first picture with reference to bones and soft tissues as seen in Fig. 2 (it is a matter of course that the time of exposure must vary, brief, for the oblique; and longer, for the perpendicular direction), while the pictures of the foreign bodies remain visible. It is true that not every foreign body is reproduced by a double image, but the explanation of this would take a too wide range and will be considered at a future date in a separate paper.

Viewing Fig. 2 in general, we cannot see the first picture of the bones at all, because it is destroyed by the second picture originating from the perpendicular rays, and accordingly the picture of the bones appears to be very distinct and sharp. If we consider how much emphasis is laid upon the necessity of immobilizing the parts to be skiagraphed and of having the tube remain stationary in its original place (many devices and procedures are described for attaining this end2) in order to obtain good negatives, the findings as described before may prove of some interest. Even the soft tissues are fairly distinguishable. With reference to the details of Fig. 2, we will consider first the picture of the two pins crossing each other (between the metacarpi of the fourth and little finger). The respective distances of the pins from the plate can be easily differentiated by their skiagraphical appearance. Thus we see that the head of the longer pin is depicted sharper (i. e., nearer to the plate) than its pointed end; furthermore, we notice that the head of the second pin, considerably foreshortened, appears to be faded and indistinctly outlined, which means that the head of this pin is located behind the bone in the dorsal soft tissues, far from the plate, and its shadow is projected upon the plate through the bone; we can also see that the bone itself somewhat dulls that part of the pin which is farthest from the plate, since as soon as its picture emerges from under the bone picture it grows darker, i. e., brighter, until finally the pointed end appears very distinct and sharply outlined, showing its approach to the plate.

Besides the secondary sharp picture of the two pins under discussion, we see on the metacarpal bone of the fourth finger the most important part of the primary picture.

If we extend the primary picture of the longer pin in a distal direction (a) it will strike the head of that pin, consequently the primary and secondary

The author's paper On the Relation of the X-Rays to Differ out Dyss read at the Third Congress of the Deutsche Röntgen Gewilselaft at Berlin (1907) will shortly be published.

²Some of which are carried to extremes; thus, for instance, the compression diaphragm is sometimes used when not indicated. ²Only econogly longer, hecause it does not lie as obliquely as the other

pictures meet at one point (at another place on Fig. 2 it can be plainly seen how the two heads in the pins primary and secondary picture remain united). From this we may draw the inference that the head of the pin is located very close to the plate. The picture of these heads remain united, no matter in what degree of obliquity or from what direction the x rays fall upon the hand, and thus enabling us to correctly interpret the accurate localization.

The primary, faint picture of the pointed end (b) appears to be far away from the pointed end of the secondary picture (b), proving that its location is farther from the plate in the deeper tissues and more remote than the pointed end of the other (shortened) pin (c), but not as far away as the head of the same pin (d), which appears to be very far off. That this is so can be indubitably seen if the converging primary and secondary pictures are extended by a line; the extended line will meet at X.

The primary picture of the apparently shorter pin is not complete, but the part presented is sufficient to demonstrate that the pictures of the pointed end cannot meet; in its diverging course it may be traced even on the picture of the blue pencil, also indicative of the difference of obstruction offered

by the blue lead and needle.

In reference to the picture of the whole needle (crossing the metacarpus and basal phalanx of the little finger in an oblique direction), it appears to be very distinct and to take the course from the dorsum into the vola; its distal end (eye) is not as sharp as its proximal half. Now, if we want to estimate the distance of the point of the needle (shown to be in the palmar tissues) from the plate, i. e., its depth in the tissues, we have to look again for the primary picture of the needle, which is to be found in the soft tissues beside the basal phalanx of the fourth finger.

The two pictures do not meet, only their extended lines; if compared to the pictures already described it may be said that the point of the needle is closer to the plate—i. e., the surface of the skin—than the point of that pin, whose much shortened picture we have seen and considered previously and which also runs from the back to the palm of the hand (see

Fig. 2 and sketch of pins).

The course of the primary picture is not visible owing to a very delicate and faint depicting of the shadow of the needle, but would not be visible even with a sharp picture of the needle, as the small shot representing a relatively large obstruction, does not allow the primary picture to show to advantage.

On the end phalanx of the fourth finger we also see the primary and secondary picture of the externally located needle; the very faint primary picture runs almost parallel to the secondary (sharply outlined) one, indicating that the position of this needle approximates the horizontal line. Finally we see a double picture on the distal end of the ulnardiaphysis, the distinct outline of which point to a position under the bone. The two pictures meet at their distal points, and their diverging course can be followed up to their ends, and in the primary picture even up into the shadings of the soft tissues. This picture resembles much the one we have seen (a)

in the crossing pins, and, just as we inferred there, from the meeting of the primary and secondary picture, that the head of the pin must be close to the plate, i. e., not deep in the soft tissues, we may also say the same thing regarding the distal end of this needle under discussion; in reference to its pointed end, however, we see that it is more deeply located, and consequently the position of the needle must be oblique. As to the rest of the pictures of the foreign bodies, there is nothing of importance to add to the data obtained from interpreting the pictures analyzed so far. Distance, position, and location can all be nicely differentiated from a correct interpretation and reading of the pictures.

Fig. 2 has been presented, as before mentioned, with the only object of conveying a clear idea of the behavior of the sensitive plate upon making a skiagram from two different directions, i. e., if two pictures are projected upon each other; the question is whether the data thus obtained really improve our ability of drawing an inference as to the position, location, and distance from the plate of the foreign bodies contained in the tissues, and if they do, to what extent do they add to the information already

obtained from Fig. 1.

Fig. 2 is the result of a number of experiments, but not a complete result, since not every foreign body shows a double picture (the explanation of which will be given at some other occasion). One point, however, should be emphasized, namely, that the anticathod should always move in one plane when skiagraphing for a double picture, otherwise

we may get altogether different effects.

Furthermore we learned from these experiments that the sensitive plate, after having been once acted upon by the x rays, is still capable of producing another skiagram. This experience is especially of importance in skiagraphing children, who are often very restless, and especially at the beginning of an exposure. In such cases we did not remove the plate, but instead protracted the time of exposure, and, as a result, we got a definite, sharply outlined picture. If, however, that restlessness should begin after exposing for some time, when the chemical action of the rays upon the sensitive film has been protracted and therefore too intense, the picture thus produced will be faded and blurred, and no method of intensifying can correct it. It might also be mentioned that the length of the excursion in moving the tube should be great, and that the moving should not be done carelessly, for we may thus get pictures entirely misleading.

Conclusion.

In conclusion, we wish to mention one more point. The hand under discussion contains many different foreign bodies scattered all over and not of the same kind; in such cases it is very hard to obtain a picture satisfactory in every respect. Ordinarily we have to deal only with but one foreign body, or, if with many, they are usually of the same kind, and thus facilitates our ability to interpret the plate.

This paper, to repeat it, presents the product of an experiment, and is not theory, but a statement of facts based upon experiences which are instructive

and worthy of consideration.

BACTERIAL TREATMENT OF ERYSIPELAS.

BY HARRY A. DUNCAN, A. B., M. D., Philadelphia,

Director of Clinical Laboratory at the Samaritan Hospital,

AND G. MORTON ILLMAN, M. D., Philadelphia,

Instructor in Medicine at the Temple University.

Almost every worker in bacterial treatment of disease who has contributed to the literature of that subject has laid more or less emphasis upon the fact that good results are achieved in a large proportion of the chronic cases, such as acne, tuberculosis, etc., but that little can be expected of such treatment in acute infections. Acute gonorrhea is the most mentioned example.

In an article recently published we noted some encouraging results in the treatment of boils and carbuncles with dead microorganisms. Erysipelas has vielded so little to treatment in the past that it is not wholly strange that many medical men have abandoned therapeutic remedies, used supportive treatment, and hoped for a living patient after the disease had "run its course"—i. e., developed sufficient specific resistance in the body to check further spread of the disease.

We have treated three cases of erysipelas by the injection of dead streptococci with apparently uniformly good results. We realize the futility of attempting to draw lessons from three lonesome cases, and only report them for their "face value." In this manner we hope to hear from other cases.

The dose in these cases varied from 30,000,000 to 60,000,000 dead streptococci. Dr. Leedom and Dr. Gradess have kindly furnished us with the following brief case reports. The first two cases are Dr. Lee-

dom's; Case III is that of Dr. Gradess:

CASE I .- Miss B., age twenty-five. Sent to the Samaritan CASE I.—Miss B., age twenty-five. Sent to the Samaritan Hospital on March 29, 1908, for the removal of retained placenta. On the second day a bright red spot developed on her nose, which during the next twelve hours had spread over the right side of her face and forehead. Simultaneously with the appearance of the red spot there was a rise of temperature to 101.4° to 102° F. This local infection was plainly erysipelatous and rapidly spread to the left side of the face and scalp. The temperature climbed to 103° F. Quinine sulphate, gr. v, and Tr. ferri chlor., m xx, every four hours, with local applications of ichthyol ointment hought to improvement either in condition or temperature. brought no improvement either in condition or temperature. I asked Dr. Duncan to see her on the fifth or sixth day, and

I asked Dr. Duncan to see her on the fifth or sixth day, and he suggested sterilized streptococi. A dose of 50 million was given. Twelve hours later the temperature dropped, and from that time the recovery was uneventful.

CASE IL.—W. H., age nincteen, was referred to the Samaritan Hospital with the diagnosis of typhoid fever. His face was swollen and fierry red; eyelids edematous; temperature on admission, 100.6° F., which advanced to 103.4°

F. He was nauseated, and suffered from chills and fever. He was isolated and given the routine treatment for ery-He was isolated and given the routine treatment for erysipelas, viz., quinine and iron, with no benefit. I had seen such good results from Dr. Duncan's treatment that I asked him to give this young man a dose of sterilized cocci. He was given the treatment on the third day of the disease, and on the morning of the following day his temperature. ture was very nearly normal and a marked improvement noted in his condition. He felt so much better that he in-

noted in his condition. He felt so much better that he insisted on going home.

Case III.—B. C., female, aged twenty. I called to see her on May 12, 1008, and found her suffering from general aches and pains, commonly called "a cold." There was some tonsillar and pharyngeal injection. I called the following day and found a well marked tonsillitis. I prescribed and did not call on the following day. On the 15th I was seen all call on the following day. On the 15th I was seen all call on the following day.

right lower eyelid, with a bullous eruption on the right side of the nose, extending somewhat downward toward the nasolabial fold and slightly on the left side of the nose near the inner canthus. A diagnosis of erysipelas was made, and the usual treatment given, viz., ichthyol locally, which was later changed to a saturated solution of magnesium sul-The temperature ranged to 104.2° F. The patient seemed to improve for two or three days. There was no extension of the inflammation, and there was considerable remission in temperature.

Toward the end of the first week I noticed a slight chemosis of the left lower eyelid, which later took on the characteristic appearance. This spread to beneath the chin, to the

istic appearance. This spread to beneath the chin, to the ear, and merging on the opposite cheek passed completely around the neck. The temperature ranged to 104.1° F.

For the better part of the following week no progress was noted in the arrest of the disease. The inflammation spread continuously down the chest, reaching to below the mamma, and on both arms. The temperature ranged to 105.2° F, and the patient was frequently delirious.

In the latter part of the second week I called in Dr. Harry Duncan, who injected dead streptococci. Some reaching was noted on the day following the injection. There

tion was noted on the day following the injection. was a considerable remission in temperature on the second was a considerable remission in temperature on the second day. No further extension of the inflammation occurred on the chest, and there was a marked drop in the temperature, with no subsequent rise. The temperature was 99.2° F, on the third day. Some extension of the inflammation occurred on the arms, but no further rise of temperature was noted. The temperature was normal on the fourth day, and there was no further extension of the inflammation. Recovery was uneventful.

LXXIX.—How do you treat sick headache? (Answers due not later than October 15, 1908.)

Whoever answers one of these questions in the manner most satisfactory to the editors and their advisers will receive a prize of \$2.5. No importance volutever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not recurrent) that the answers be short; if practicable, no one answer to contain more than six hundred reports.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded anether subscrivers or not. Into prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. The prize of \$25 for the best essay submitted in answer to question LXXVI has been awarded to Dr. Bewerley Behinson of New York whose articles the agent of the property of th

Robinson, of New York, whose article appeared on page

PRIZE QUESTION LXXVI.

THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

(Concluded from page 511.)

Dr. Alfred S. Jaeger, of Indianapolis, Ind., writes: Although diagnosis is without the scope of this paper, it is so all important we cannot refrain from emphasizing the fact that upon an accurate diag-

nosis depends primarily the success of whatever line of treatment may be followed. Therefore be-

fore instituting any treatment we should be reasonably sure that it is acute articular rheumatism and not one of the multitudinous conditions frequently mistaken for it.

The first step in the treatment should be absolute rest. The patient must be put to bed and kept there regardless of what special joint or joints are involved. This is not insisted upon solely to keep the affected joints quiet, which, of course, is necessary—and in restless or nervous patients it may at times be advisable to lightly splint the parts to insure this—but in a great percentage of cases this absolute rest in bed undoubtedly lessens the tendency to progressive joint involvement, and is our greatest safeguard against cardiac complications.

At the onset the entire gastrointestinal tract should be thoroughly purged, preferably with sa-lines, to be repeated frequently enough to insure soft stools throughout the course of the disease. Heat should be used in whatever form available. My patients are put to bed between blankets, and from six to eight hot water bags or glass bottles, suitably protected, are distributed in the bed. If these are not obtainable hot bricks, irons, or bran bags, or anything which will retain heat, is used instead. The object is to keep the patient as hot as can be comfortably endured. A hot bath may be given once or twice daily, the patient remaining in about fifteen minutes, when the general condition does not counterindicate it; but it must be given with caution, as collapse in the bath may occur when least expected. In hospitals the hot air treatment is available, and daily treatments of one hour duration at a temperature of from 250° to 400° F. may be given with good results. essential point is that heat must be applied continuously, as it greatly aids in the rapid elimination of toxic materials, besides abating pain and inflammation. Bier's hyperæmia method has been also used by me with decidedly good results.

The affected joints should be dressed with some of the following solution:

Gauze should be saturated with this mixture and laid entirely around the parts, over which is placed absorbent cotton or wool, and the whole covered with oil silk, rubber sheeting, or newspaper, if nothing else is obtainable, to make an impermeable dressing, and applied three times daily or oftener. When the pain is extremely severe, tincture of opium, 4 drachms, may be added to the solution; but, on the whole, opium in any form is counterindicated, though in some cases we are compelled to use it to control pain. The above mixture has eased a patient more quickly than any application the writer has ever used.

As in malaria quinine is our specific, so in the treatment of acute articular rheumatism do we find our sheet anchor in salicylic acid or one of its derivatives. Which form of the drug is used is a matter of personal preference. My own experience has been mainly with sodium salicylate and acctosalicylic acid, commonly known as aspirin. I feel that

the best results are gained by getting the patient saturated with the drug as quickly as possible. To gain this result I give doses which to some may seem dangerous, but I have yet to see bad results when a pure drug is used. The patient is, however, always carefully watched for idiosyncrasy. Sodium salicylate is usually prescribed in 15 grain doses hourly for four to six doses, and then every two to three hours, repeating the same daily until the patient is completely under its influence, when the dose is reduced. Aspirin is given in 10 to 15 grain doses every two hours. The latter is perhaps the preferable of the two, as it may be given for a longer period of time without producing tinnitus and nausea. When symptoms subside the dose and frequency are lessened. It is naturally understood that the form, frequency, and amount of the drug used is governed by the demands of the individual case. In fact, throughout the treatment of this disease, individualism is an important factor. The point in giving salicylates is to give enough, and to give them for weeks after all symptoms have disappeared.

The diet should be bland. As this disease is an acute infectious disorder, we see no reason why the diet should be any different than that given in other like conditions. The object should be to give easily assimilated and nourishing foods. Personally I have depended mainly on milk, buttermilk, and kumyss; but here again the individual case must be considered, and such diet given as best agrees with the patient. As much pure water as possible is to be given, but alcohol internally we believe is harmful in this disease at all times.

Electricity, massage, or rubbing of any kind are most certainly counterindicated until all pain and swelling has subsided. Such treatment only tends to further irritate a part already inflamed. It is well known that stimulation is bad for any acutely inflamed joint, and we cannot see why it would be less harmful to an acutely inflamed rheumatic joint. In a few cases during convalescence passive motion may be indicated, but when this is done it should be performed most delicately.

Alkalines may be given with the salicylates if desired. The writer does not use them as a routine. When they are prescribed, the bicarbonate or benzoate of soda or potassium acetate is given in three to five grain doses, two or three times daily or oftener, and the urine watched for excessive alkalinity. The so called alkaline treatment of acute articular rheumatism has not proved itself of special value in the writer's experience.

Cardiac involvement cannot be discussed here as carefully as its importance demands. It will occur at times in spite of the most approved and careful treatment. The heart must be closely watched throughout the course of the disease, and the slightest variation considered as a possible forerunner of serious trouble and treated accordingly. As before mentioned complete rest is our greatest safeguard, and in the writer's practice it has not been common to encounter cardiac involvement in a previously healthy heart, when his orders have been conscientiously carried out. When it does occur the treatment must be such as the individual case demands. Endocarditis and myocarditis are the most frequent.

An ice bag to the left chest and absolute rest has proved most effective, although blisters and the remedies usually recommended for these conditions have also given good results. When heart involvement occurs the salicylates are usually stopped, but the writer does not believe that salicylate medication has a tendency to increase the frequency of cardiac involvement, or make it more serious when it does occur.

Hyperthermia is rare, as the salicylates usually control the temperature. When there is fever of over 104.5° F., not reducible within twenty-four hours, associated with delirium or muttering, it is reasonable to presume that there is cerebral involvement, and the ice cap, etc., should be used. Happily this is rare, as it usually ends fatally.

During convalescence the patient is usually given from three to fifteen grains of potassium iodide in combination with iron, quinine, strychnine, and

arsenic, three times daily.

In summing up the successful treatment of acute articular rheumatism, I would say that rest, heat, and the administration of some salicylic acid preparation in sufficient quantity are of paramount im-The individualism of the case must alportance. ways be borne in mind. The patient should not be permitted to leave the bed for a least a week after all symptoms have subsided, and not for four weeks or longer if there has been any cardiac involvement. If he disregards this advice he should be given emphatically to understand that he does so at his own risk. The salicylates should be given for weeks after the patient seems to be apparently well, and he must be continuously warned of the serious remote effects which may follow a too early return to normal activity.

Dr. H. F. and Dr. C. L. Sigler, of Pinckney, Mich., remark:

Our experience with the treatment which we will discuss has been so uniformly successful that we have discarded practically all other remedies in its favor

It is not in the least an exaggeration to say that all the acute cases we have treated by this method were cured, the subacute cases either cured or greatly relieved, and the chronic cases much relieved or

in a fair number of instances cured.

The method consists in the application of dry, hot air, either to the affected joint or preferably to the whole body. The apparatus used is one manufactured by a well known firm and is heated by gasoline burners. The body apparatus consists of a large asbestos lined drum or oven, capable of being heated to 500° F., or even higher, although this intense heat is seldom used, the general custom being to maintain the temperature between 350° and 400° F.

The patient clothed in a bath robe, heavy stockings and mittens, is well wrapped in blankets and placed on a carriage which is then rolled in so that

only the patient's head remains outside.

As soon as he begins to feel the heat or commences to perspire, iced cloths are placed across the forehead and copious drinks of cold water are administered, thus inducing free perspiration. This

is evaporated so very rapidly on account of the dryness of the air, that the bodily temperature is raised but slightly if at all.

After the treatment, which continues from thirty to sixty minutes, each day, the patient is quickly sponged with warm water and soap, and after drying is rubbed with alcohol or some liniment. An application frequently used contains menthol, oil of wintergreen, and salicylic acid. The patient is then returned to bed where he continues to perspire profusely for one hour or more, when he has a drying rub and if permissible is dressed.

This treatment literally "washes the blood," removing the poisonous material responsible for the symptoms, as is evidenced by the reduced temperature, cessation of pain, and the restored normal appearance of the joint. The beneficial effect of the treatment is usually noticed after the initial "baking," although of course the result is not so quickly

shown in subacute or chronic cases.

A week's treatment frequently suffices in acute cases, although the treatment is usually continued for a few days after the disappearance of the symptoms. Drugs are seldom used in the acute cases, although some mixture of potassium iodide is occasionally given in the more chronic cases, especially if accompanied by deposits in the joints. When the disease is confined to one joint, as the ankle or knee, a smaller apparatus accommodating only this part may be used, but the results are not so striking as when the large apparatus is used.

These conclusions are not based upon a small number of cases, but from a rather extended experience during a number of years, in which period we have almost entirely abandoned the drug treat-

ment of acute articular rheumatism.

Dr. Charles S. James, of New York, writes:

A patient suffering from acute articular rheumatism should be placed in a suitable apartment which is well supplied with fresh air having a temperature of 70° F. The bed should be of narrow pattern and easily accessible from both sides. All draughts should be avoided and the patient should wear flannel underwear and use flannel sheets for covering.

Nitrogenous food and alcoholic stimulants must be discontinued.

A limited diet, consisting of milk and carbonated water or butter milk should be given until the acute stage is passed. If the temperature is over 105° F, a cold sponge or tub bath is indicated, and can be repeated every two hours until the temperature has been reduced. Local applications of hot packs covered with oil silk applied to the affected joints are very comforting to the patient.

Medicinal treatment is commenced by giving calomel, gr. 10; pulv. jalap cc., gr. 15; followed by a saline cathartic in a few hours. Sodium salicylate is the most satisfactory drug, and is used in doses of 10 grains to 20 grains every two hours until the pain has subsided. If the stomach does not tolerate the salicylate it may be given by rectum in larger doses as an aqueous solution. Infusion digitalis can be added to the salicylate if there is heart complications. For the severe pain a hypo-

dermic injection of morphine sulphate, ½ grain, can be used but not repeated unless absolutely

necessary

Encourage the drinking of large quantities of pure water to which has been added an alkaline as potassium acetate to the amount of one drachm per

Massage is beneficial and soothing even if painful at first, whereby the function of the muscles and joints may be gradually restored to normal. Oil of gaultheria, one part, to five parts of olive oil may

be used for massage.

Following the acute stage tincture of iron chloride in half drachm doses three times a day is used as a tonic, also potassium iodide, gr. 10, three times a day in milk which aids in the absorption of the exudate around the joints. Electricity is commonly used at the present time but has no effect on the rheumatism but acts as a stimulant to the muscles and nerves.

Dr. W. M. Burwell, of Chincoteague, Va., remarks:

Put the patient to bed in the best located and best ventilated room in the house, but free from draughts, and keep him there from one to two weeks after fever, pain, and swelling have disappeared, and have a gentle and capable person to act as nurse. The bed should have a smooth and moderately soft mattress. A flannel nightgown is most suitable. He may lie between blankets or sheets as he prefers, but one or more blankets should be used for cover, as the temperature of the weather may demand. He should be allowed pure water freely at all times. The diet during the febrile stage should be pure milk, broths, and soups, but meat should be interdicted. Food should be given at stated intervals four or five times in the twenty-four hours. As convalescence is established a more liberal yet simple and easily digested diet should be allowed.

The affected joint or joints should be wrapped in absorbent cotton or cloths saturated with lead water and opium, and the whole covered with oiled silk

or oiled muslin.

In case of hyperpyrexia there is but one treatment; the application of cold. As soon as the temperature begins to rise rapidly above 105° F., a large ice cap should be placed against the head and kept there until the temperature is sufficiently reduced and a general sponge bath with ice cold water be given every one or two hours.

When necessary for acute pain, but only when necessary, a sufficient dose of morphine sulphate and atropine sulphate, say a quarter of a grain of the former and 1/150 of a grain of the latter, should be given hypodermically to afford relief. It will be unnecessary to repeat this often if the subsequent

treatment is properly carried out.

At the commencement of the treatment unload the bowels by the administration of calomel, 4 grains; sodium bicarbonate, 4 grains; and podophyllin, two thirds of a grain, at one dose, or by a liberal dose of magnesium sulphate. And during the whole course of treatment keep the bowels open by aromatic fluidextract of cascara sagrada or by a pill of aloine, one quarter of a grain; belladonna, one eighth of a grain; strychnine, one sixtieth of a grain; ipecac, one sixteenth of a grain; given best at night, but two or three times a day if necessary.

Give sodium salicylate in from fifteen to twenty grain doses, best in solution, with a liberal quantity of water every two hours till pain is relieved; then eight or ten grains every four or five hours, till fever and swelling are relieved; after which time continue the drug in four or five grain doses three times a day for a week or ten days. After fever and pain have subsided a tonic treatment should be added consisting of elixir of iron, calisaya, and strychnine, and continued as long as the case demands, which must be determined by the judgment of the physician.

Correspondence.

LETTER FROM TORONTO.

The American Public Health Association.—A Revised List of Officers.

TORONTO, September 5, 1908.

In my last letter I did not include the transactions of the last day of the meeting, and it was an error to state that Dr. Hodgetts, of Toronto, was elected president. The election of officers took place on the last day of the meeting, and the place of meeting in 1909 was declared to be Richmond, Va. The officers are: President, Dr. Gardner T. Swartz. of Providence, R. I.; first vice-president, Dr. R. M. Simpson, of Winnipeg, Man.; second vice-president, Dr. Jesus Chico, of Mexico; third vice-president, Major Charles F. Mason, of the U. S. Army; secretary, Dr. Charles O. Probst, of Columbus, O.; treasurer, Dr. Frank W. Wright, of New Haven, Conn. At this session of the meeting the following resolution was unanimously passed:

Resolved by the American Public Health Association that it heartily recommends to the American Congress the passage of such legislation as may be intended to enlarge the scope and increase the efficiency of the Public Health and Marine Hospital Service. To this end the association believes the power of the service should be increased, that provision should be made for the retirement under pay of the members of the service, and that the salaries of the said members should be made commensurate with those of the medical service of the army. The secretary shall send a copy of this resolution to the chairman of the House Committee on Interstate and Foreign Commerce and to the corresponding

committee in the Senate.

Typhoid Fever in the Middle West was the title of a very interesting paper contributed by Dr. S. J. S. Pierce, of Winnipeg. The facts were collected from the experience of the Winnipeg General Hospital, which was incorporated in 1875 with fewer than forty beds. It now has three hundred beds and has received 35,000 patients, of whom 4,800 had typhoid fever, 3,500 coming from the city of Winnipeg proper. Out of 4,605 cases, the statistical reports of which were examined, 3,530 were in males and 1,075 in females. As there was no such disproportion in the population, the conclusion drawn was that men had been more exposed to the disease. The average age of these 4,605 patients was: Males, twenty-six years; females, twenty-one

The month in which the greater number of cases developed was September, one fourth of all the cases in a year being recorded in that month. It has been a matter of common observation that typhoid fever is most prevalent among recent arrivals. In 3,170 recorded cases, thirty per cent. of the patients had been in the country less than a year; fifty per cent. had been in the country less than two years. The patient usually entered the hospital on the ninth day, and the temperature was then at the maximum in half the number of cases. The average of the maximum in 779 cases was 103° F. In cases of moderate severity, fifty-three per cent., the temperature remained high for eight or nine days after admission, reaching normal twenty-five days after the onset of the disease. The average duration of fever in 628 cases was found to be twenty-eight days. In twenty-six years, out of 4,605 cases, 573 ended fatally. In the early years at the hospital the mortality was high. In 1884 it was twenty-eight per cent. In 1892, however, it was only five per cent. For the past three years it has been ten per cent. The mortality among the females has been slightly less than among the males. Of patients under ten years of age, eight per cent. died; under twenty, ten per cent.; under thirty, eleven per cent. The mortality rate has been high in the winter and spring months, when the number of cases is the smallest.

Dr. R. M. Simpson, chairman of the Manitoba Board of Health, and Dr. A. J. Douglas, M. H. O., Winnipeg, contributed a paper on Typhoid in Winnipeg. This paper went at length into the steps taken to deal with epidemics. In the late nineties the water company's plant was bought out and the present system of artesian wells adopted by the municipality. In spite of the fact that the water supply was above suspicion, the typhoid rate rose, and Winnipeg presented the somewhat anomalous picture of a city with a pure water supply and a high typhoid rate. In 1902 began what might be called Winnipeg's second boom. The population doubled in three years. Again, in an aggravated form, were repeated the experiences of 1881 and 1882. In 1902 there were 356 cases; in 1903, 489; in 1904, 1,275; in 1905, 1,606; in 1906, 1,174; in 1907, 307 cases. In 1904 the abolition of box closets took place, and for them were substituted brick and water tight pits where sewers were not laid. January, 1905, there were in the city 6,153 box closets and 189 pits. At the present time there was one box closet is old Winnipeg and about sixteen in the old suburbs. There were yet 1,650 brick pits. In the present year there had been only 160

A paper was read by special request of the programme committee on The Mortality and Mortality Statistics of Typhoid in the Middle West States. This had been especially prepared by Dr. White at the request of the programme committee, and showed the greater prevalence of typhoid in the Middle States than anywhere else except in the Southern States.

A study of typhoid in Richmond, Va., was presented by Dr. Ernest Levy, and Dr. James T. Bowles, chemist of the State Hygienic Laboratory,

dealt with the investigation of an epidemic of typhoid fever at Sheboygan, Wis.

In discussing the typhoid fever patients, Dr. Macdonald, of Brandon, Man., emphasized the dangers of the common house fly in spreading the disease. Dr. Wood said that the latest movement in Washington to study the disease was the rigorous registration of all places where food was prepared, so that they might be regularly inspected. There was also to be a systematic inspection of laundries and stables. Dr. Swartz pointed out that health officers need not be disappointed if it was not always possible to trace the source of the disease, as it might have started from the farm and been carried in the milk supply, although the disease might not have shown itself there. In Minnesota, Dr. Hill said, without waiting to trace the source of the outbreak, they threw a tourniquet around the area where the disease appeared and started on a campaign of education in the town or district where the outbreak occurred.

Poverty and Tuberculosis was the title of a paper read by Eugene T. Lies, general secretary of the Associated Charities, Minneapolis, Minn. He dwelt on the evils of quack advertising and the fact that the better newspapers were now excluding this from their columns. In one case in Minneapolis, one of these quack scoundrels offered to give a written guarantee to cure a poor man of tuberculosis for \$50 cash paid in advance. The offer was not accepted, and the man died nine hours afterward.

Therapeutical Hotes.

Treatment of Tuberculous Laryngitis.—In the Annual Report of E. Merck for 1907, Barwell's method of treating tuberculous laryngitis by carbolic acid in combination with lactic acid and formaldehyde is cited. It consists in painting with the following solution:

| B | Carbolic acid, | 3x; |
|---|---------------------------|-----------|
| | Lactic acid, | 3vi, 3ii; |
| | Solution of formaldehyde, | 3vii. |
| M | | |

The quantities are to be taken by weight.

Induration in Lupus Erythematosus.—Kanoky (Medical Record), in such cases, favors salicylic or pyrogallic acid, suspended in collodion:

| ĺŝ | Salicylic acid. | | | | |
|----|------------------|-----------|----------|----------|-------------|
| | Pyrogallic acid | , | | IO.O | grammes; |
| | Collodion, | | | 100.0 | grammes. |
| M. | et sig.: Shake a | and apply | at night | with a c | amel's hair |
| 1. | | | | | |

If this causes too much irritation it should be temporarily discontinued and a soothing application substituted, such as:

| \mathbf{R} | Zinc | oxide, | , | | | | | | | ٠ | | | | | 60.0 | grammes | |
|--------------|-------|--------|---|------|--|---|--|---|---|-------|--|---|---|---|-------|---------|--|
| M | Olive | oil, . | | | | ٠ | | ٠ | ٠ | | | ٠ | ٠ | ٠ | .40.0 | grammes | |

If the lesions are in the noninflammatory, pale, and anemic state he advises painting them with a strong iodine preparation, repeating it three times each week. Internally he administers salicin, alternating with quinine, commencing with 1.0 gramme after each meal, and gradually increasing.

NEW YORK, SATURDAY, SEPTEMBER 19, 1908.

THE OYSTER AS A DISTRIBUTOR OF DISEASE.

Now that the oyster season has fairly opened, many apprehensive people are doubtless refraining from eating oysters in the raw state, pending authoritative and conclusive assurance that the oysters supplied to our markets at the present time have incurred no chance of contamination with the germs of disease, especially with the germ of typhoid fever. A few of these people—those who do not like cooked oysters-are subjecting themselves to a real deprivation. They have lost what little brief faith they may once have had in the alleged corrective virtue of lemon juice, and they have simply resigned themselves to bearing their loss with whatever equanimity they may. In the interest of such persons, as, indeed, in that of the entire community, there should be forthcoming some ample guarantee of the freedom of our oysters from pollution.

The purveying of oysters must be largely a matter of interstate commerce, and we think the people are entitled to the intervention of the Federal authorities in regulation of the trade on the score of care for the public health. As regards our supplies in New York, it is understood that the sanitary officials of the city have given out a general statement to the effect that our oysters may be eaten raw without fear of their being contaminated with pathogenic germs. It would prove more satisfactory, we think, if certain specific measures were enforced to prevent

or overcome such contamination. This course has been adopted in Paris, as we learn by the *Progrès médical* for August 29th. Acting on the strength of a sanitary report by M. Chatin, vice-president of the Council of Public Hygiene and Salubrity of the Department of the Seine, the Paris prefect of police has issued certain specific decrees.

One of the prefect's decrees forbids the exposure for sale or the delivery to consumers of oysters until after the exterior of the shells has been freed of animals, vegetables, and detritus by brushing or by some other means. This procedure, with all its vagueness in the matter of "some other means" (tout autre moyen), applies, we take it, only to the freeing of the shells from gross adventitious substances, and does not touch intimately the matter of getting rid of pathogenic microorganisms; but the decree is good so far as it goes.

More to the point is the second article of the prefect's proclamation. It ordains that dealers in ovsters must not employ, either in the soaking ("fattening"?) or cleansing of oysters, any other water than that which is potable, such as is used by the public for drinking purposes, but that, in case of need, they may salt the water. In the third article the prefect expressly forbids the employment of salt which has been used in the transportation or preservation of fish or any other article of food for the purpose of salting the water used in the soaking or cleansing of oysters. In article 4 dealers who open oysters for delivery to consumers are forbidden to make use of utensils which are not constantly kept clean, and they are forbidden to wash oysters already taken from the shell. These requirements do not appear to be very far reaching; indeed, they might be intensified to the general advantage.

THE ÆTIOLOGY OF HÆMOGLOBINURIC FEVER.

M'Cay (Indian Medical Gazette, December, 1907) publishes the results of some studies on the ætiology of hæmoglobinuric fever which were undertaken from the point of view of hæmolysis. He found that in health the action of sulphates upset, for a time at least, the osmotic equilibrium that normally exists between the red blood cells and the plasma in which they float. When quinine sulphate, magnesium sulphate, or dilute sulphuric acid was added to the blood plasma, a very serious decrease was obtained in the total amount of inorganic salts in the plasma, implying in turn a serious decrease in its osmotic tension. The red cells being impermeable, no change takes place in the number of their inorganic molecules; but by endosmosis water

passes into them and causes them to swell up, and, if the decrease in the plasma is sufficient, eventually to burst and extrude their hæmoglobin. Dr. M'Cay offers the following hypothesis, which appears to be reasonable and tenable: In blackwater fever the hæmolysis is due, first, to the injury to the stroma of the red blood corpuscles by the malarial parasites; second, to the presence of an hæmolysin; and, third, to the administration of sulphates. The first two factors may precipitate the attack if they are severe enough, but in other cases the third factor will have to be added to produce the attack. According to this hypothesis and the observations recorded, it would be possible for quinine, if given in the form of the sulphate, to produce an attack of hæmoglobinuria if the amount administered was great enough and the red corpuscles were injured otherwise than by the presence of an intracorpuscular parasite. Dr. M'Cay found on further search that, while the sulphates caused a lowering of the resisting power of the red blood corpuscles to hæmolysis, the chlorides caused an increased resistance to hæmolysis. In every experiment in which quinine hydrochloride was used, particularly when combined with sodium chloride and dilute hydrochloric acid, no fall was noted in the salts of the plasma; but usually there was a marked rise of the inorganic salts in that fluid. As malaria is the underlying factor in the ætiology of blackwater fever and as quinine must be given to remove that cause, it is rational to avoid giving sulphates and to administer quinine in the form of the hydrochloride or the acid hydrochloride. In addition to the sulphates, large quantities of alkaline carbonates or compounds of alkalies with vegetable acids, also potassium salts, should be avoided. These substances all tend to lower the number of inorganic molecules in the blood plasma, and, therefore, to bring the red corpuscles nearer to the hæmolytic point. On the other hand, the chlorides have the opposite effect, and tend to raise the resisting power of the red blood corpuscles.

In a comment upon the results of the work of Dr. M'Cay, in the Indian Medical Gazette for February, 1908, C. P. Lukis advances the theory that the Leishman-Donovan body (Leishmania Donovani) is the hitherto undiscovered factor in the ætiology of blackwater fever. He contends that the geographical distribution of hæmoglobinuric fever in India is identical with that of the occurrence of kala-azar. But what will Dr. Lukis say of the cases of hæmoglobinuric fever which occur in the West Indies, in the United States, and in Airica—that the Leishman-Donovan body is present there, but as yet undiscovered? The Leishman-

Donovan body may be a cause of hæmoglobinuric fever, but it is not the sole cause, and we gather from reading Dr. Lukis's communication that the latter is what he wishes to state.

"ENDEMIC FUNICULITIS."

Under this hybrid and rather indefinite name Castellani (Annali di medicina navale, 1908, 4, 5; Presse médicale, September 2d) describes what seems to be a peculiar disease of the spermatic cord. He says that it has not yet been described in any textbook, although it is very well known to the physicians of Ceylon and southern India, where of late years it has seemed to assume a truly epidemic character. The onset is sudden and marked by chills, nausea, and sometimes vomiting. At the same time the patient feels severe pain throughout the spermatic cord and in the epididymis, and there is moderately high fever. At this period examination reveals a swelling in the inguinal region, following the course of the spermatic cord. It is hard in consistence, and pressure upon it causes acute pain. Sometimes the epididymis is equally affected, but the testicle escapes and there is no effusion into the tunica vaginalis. The penis shows nothing abnormal. The patient's condition now becomes very grave, and one might suppose that he was dealing with a strangulated hernia, so that occasionally nothing but surgical intervention demonstrates the error. The prognosis is fatal unless an operation is performed; medical treatment is in vain, and only an early and radical procedure can save the patient. The nature of the operative intervention is not indi-

On post mortem examination, all the structures constituting the spermatic cord are found to be highly inflamed. The size of the cord is excessively increased; its circumference may be two inches or more. Though there is no effusion into the tunica vaginalis, that membrane is very much inflamed. On making a transverse section of the cord, creamy pus is found in the pampiniform plexus and in the vas deferens. Often, too, the epididymis is equally affected, but the testicle is normal. On microscopical examination, it is noticed that the walls of the veins of the pampiniform plexus, as well as those of the vas deferens, are swollen and infiltrated, their lumina being occupied by polymorphous leucocytes.

In the countries in which it occurs this affection is generally regarded as a form of elephantiasis. The author has examined the pus from the bacteriological point of view, and he has always found a diplostreptoceccus, which has been present also in the blood of the systemic circulation. In preparations stained with methylene blue, carbolized fuchsine, etc., these elements present themselves in pairs, suggesting the disposition of gonococci. They have no capsule, sometimes they are grouped in little chains, and they do not undergo decoloration by the Gram method, unless after its very prolonged application. They may be cultivated in various media, such as bouillon, peptonized water, agar, etc.

The patient's serum agglutinates the microorganisms, and the serum reaction is positive for one to fifty and sometimes even for one to a hundred, provided the disease has been running for four or five days. The serum of healthy persons or of those with streptococcic affections does not give rise to agglutination. The author thinks that the diplostreptococcus must be set down as the pathogenic organism unless further researches show that it plays only a secondary part in exciting suppuration. Apparently this disease offers one more problem in tropical medicine.

THE DANGERS OF IODOFORM.

In our issue for September 5th, in an article entitled The Dangers of Carbolic Acid Dressings, we referred to M. Salva Mercadé's remarks on carbolic acid poisoning (Archives générales de médecine, July). Proceeding to the consideration of certain other surgical antiseptics, M. Mercadé speaks of the occasional untoward effects of iodoform. We no longer dust the raw surfaces with that substance after ovariotomy, he says, and we do not blow it through drainage tubes into the depths of wounds. Nevertheless, it is still regarded as a very good antiseptic for certain purposes, and it is therefore well to be familiar with its defects.

Erythema and eczema are among the local results of its unfavorable action, but they may be dismissed with the remark that they disappear when the application of the drug is discontinued. But there are some general manifestations of its toxic influence which may appear even after the complete healing of the wound. They may be slight or severe, according to circumstances. Minor poisoning is shown by loss of appetite, loathing of food, and Then nervous sometimes nausea and vomiting. symptoms may supervene, such as insomnia, agitation, and occasionally delirium, but the temperature is not affected. Around the wound, however soundly it may have healed, there may appear an erythema that resembles urticaria. Examination of the urine reveals the presence of iodides.

The grave form of poisoning appears more suddenly. After a brief period of digestive derangements, nervous symptoms show themselves brusquely in the shape of hallucinations and delirium. The pulse is very frequent, and the urine has the same

characters as in the mild form. These symptoms may last only two or three days or they may be rather persistent. They are mitigated by the use of opium or morphine. If the poisoning becomes more aggravated, phenomena of depression ensue and the patient dies in collapse. Two other clinical types have been observed, particularly in children, the meningitic and the comatose. In the treatment it is, of course, understood that the employment of iodoform must be stopped at once. If the wound is still open it should be washed with a solution of potassium bicarbonate. Diuretics and bromides are to be given, also a five or ten per cent. solution of bicarbonate of potassium or of sodium.

Dissolving the iodoform in oil or in ether is no safeguard against the untoward effects of the drug. In a case cited by Zimmer (Thèse de Paris, 1907) as having been reported by Dresman (Beiträge zur klinischen Chirurgie, ix, 1892), a patient was treated for a white swelling of the knee by means of injections of iodoformized oil. This treatment was kept up for a number of months, the patient showing signs of mental disturbance. Finally resection of the knee joint was performed, and a mass of iodoform as large as a cherry stone was found. All the mental trouble disappeared as a result of the operation. In the Bulletins de la Société de chirurgie for May 18, 1904, Moty reported grave instances of iodoform poisoning, including a case of death, and in the same publication Delbet, while he was Trélat's interne, recorded the death of a child in consequence of an injection of iodoformized ether into a tuberculous elbow joint. But it seems that, in the ensuing discussion, M. Kirmisson could explain such occurrences only as due to faulty technique, an explanation which, we believe, is not generally regarded as satisfactory.

THE DETECTION OF THE GONOCOCCUS IN VAGINAL DISCHARGES.

Many inflammatory conditions of the female genital tract are suspected to be due to the gonococcus, and the clinician often expects the laboratory worker to make a diagnosis of gonorrhœal infection from the examination of smears made from the pus from these lesions. A paper by Dr. Fraser B. Gurd (Journal of Medical Research, May) shows what a difficult matter this is. As a result of examinations made in 113 cases, the author concludes that the study of smear preparations from fresh discharges, stained by the Gram method, is, as a rule, of little value, because of the large number of contamination organisms, the occasional presence of the Micrococcus catarrhalis, and the small number of gonococci present.

The only satisfactory method for the detection of

the gonococcus is to make cultures from the mucous membrane of the genital tract, and thus to isolate the various organisms to be found there. It is possible, in the majority of cases, to identify the gonococcus by cultural methods. Blood agar is the most suitable medium. Dr. Gurd is of the opinion that the gonococcus is of great importance in the ætiology of pelvic disease, especially of puerperal fever. He thinks that at least fifty per cent. of the women attending gynæcological clinics are suffering from infection with the coccus of Neisser. The lesions produced by the organism in question are prone to become chronic, so that viable organisms may be found years after the activity of the disease has subsided. The occurrence of pregnancy and labor is often sufficient to induce the active development of dormant organisms. The gonococcus, furthermore, is often a predisposing factor to a more serious streptococcus infection.

Obituary.

CHARLES HARRINGTON, M. D., of Boston

On Friday, September 11th, this eminent hygienist died suddenly while on a visit to England. He was born in Salem, Mass., on July 29, 1856. He was graduated from Harvard University in 1878 and from the Medical School of that university in 1881. After subsequent special studies in Leipsic, Strassburg, and Munich, he returned to Boston and became an assistant in chemistry at the Harvard Medical School. At a later period he was appointed professor of hygiene in the same institution. He was prominent in the work of the Massachusetts State Board of Health, of which he was the president. Dr. Harrington was a man of fine physique. and he was apparently at the height of his natural forces when death overtook him. He was a frequent contributor to the advancement of sanitary science, a man respected by the medical profession and by the community.

Aews Items.

Changes of Address.—Dr. E. Franklin Smith, to No. 11
East Forty-eighth Street, New York.
Yellow Fever in Cuba.—According to a despatch received at the War Department from Havana, there is one real case and one suspected case of yellow fever there.
The Society of Physicians of Canandaigua, N. Y.—A.

meeting of this society was held on Thursday, September The principal feature of the programme was a paper on Preventive Means against Mental and Nervous Dis-eases, which was read by Dr. G. Cook.

A Society for the Study of Beriberi has been organized in Tokio, with the chief of the Japanese Army Medi-cal Department as president. The object of the society is to study means of stamping out the disease, which attacked

many soldiers during the recent war.

Cholera in St. Petersburg.—According to press despatches, cholera is spreading rapidly in the Russian capital. In the four days, September 11th, 12th, 13th, and 14th, 401 new cases and 98 deaths were reported, and up to noon on Tue day, September (5th, 240 new cases and 60 deaths were reported.

Contagious Diseases in Chicago.-During the week ending September 5, 1908, there were reported to the De partment of Health 324 cases of communicable diseases, as follows: Diphtheria, 61 cases; scarlet fever, 60 cases;

follows: Diphtheria, 61 cases; scarlet lever, 69 cases; measles, 11 cases; whooping cough, 12 cases; typhoid fever, 126 cases; tuberculosis, 31 cases.

Scholarships for Women in the Medical Department of the University of Texas.—Eight scholarships of \$200 a year each have been established at the University of Texas, by Mr. George W. Breckenridge, of San Antonio. These scholarships are open to all women who are quali-

fied to enter the medical department of the university.

Winter Camp for Tuberculous Children.—Announce. ment is made by the Boston Association for the Relief and Control of Tuberculosis that the outdoor camp for tubercucontrol of Tuberculosis that the outdoor camp for tubercu

Personal.-Mme. Curie has been elected a corresponding member of the St. Petersburg Academy of Sciences.

Dr. D. J. Mackintosh, superintendent of the Western Infirmary, Glasgow, Scotland, is visiting the principal hospitals of the United States and Canada.

Dr. William Osler has been appointed Lord Rector of the University of Edinburgh.

The Naval Medical School, Washington, D. C .- The results of the recent examinations of candidates for appointment as assistant surgeons in the United States Navy show that five appointments have been made, which increases the membership of the class at the Naval Medical School to thirty members. One more examination is to be held, however, which may increase this number.

St. Mary's Hospital, Milwaukee.—Plans have been

filed for the new building for this institution, which is to be erected as a cost of \$400,000. A splendid site fronting on the lake has been selected, and it is said that when completed the building will be one of the finest in the city. Work on the building will be begun immediately, and it is expected that it will be completed in about eighteen months.

expected that it will be completed in about eighteen months. The Philadelphia College of Pharmacy.—At the graduation exercises of this institution, which were held recently, the honorary degree of Master of Pharmacy was conferred on the following men: Mr. Samuel W. Fairchild, of New York; Mr. Horatio Nelson Fraser, of New York; Mr. John F. Hancock, of Baltimore; Mr. S. A. D. Sheppard, of Boston; and Mr. William McIntyre of

Philadelphia.

A Pathological Laboratory at the City Hospital,
Newark, N. J.—The Board of Health of the City of
Newark, N. J., have created a pathological laboratory at
the City Hospital. Dr. Harrison S. Martland, assistant
pathologist to the Russell Sage Institute of Pathology, City
Hospital, Blackwell's Island, New York, has been appointed pathologist. The laboratory will be opened on
Cetaber i 1088 October 1, 1908

The South Dakota Medical Association .- At the annual meeting of this organization, which was held recently in Yankton, an association for the study of tuberculosis was formed, with the following officers: President, Dr. F. M. Crain, of Redfield; vice presidents, Dr. C. Gros, of Yankton, and Dr. A. E. Clough, of Deadwood; secretary, Dr. G. W. Potter, of Redfield; treasurer, Dr. E. C. Issenbuth of Redfield. huth, of Redfield.

The Wyoming State Medical Association.-The following officers for the ensuing year were elected at the annowing officers for the ensuing year were elected at the annual meeting of this association, which was held recently in Cheyenne: President, Dr. G. L. Strader, of Cheyenne; first vice president, Dr. R. C. Knode, of Sundance; second vice president, Dr. David Nelson, of Shoshone; third vice president, Dr. F. W. Johnson, of Newcastle; secretary, Dr. W. H. Roberts, of Sheridan; treasurer, Dr. Francis Hoff, of Thermopolis.

Scientific Society Meetings in Philadelphia for the Week Ending September 26, 1908:

Monday, September 21st. Northeast Branch, Philadelphia County Medical Society.
Wednesday, September 23d.—Philadelphia County Medical

Society.

THURSDAY, Neptember 19th.—Pathological Society; Ento-mological Section, Academy of Natural Sciences. Friday, Neptember 25th South Branch, Philadelphia

DAY. September 25th South Branch, Philadelphia County Medical Society; Northern Medical Associa-tion; Philadelphia Neurological Society.

Advisory Council to the Department of Charities, New York.—The following physicians have been appointed members of an advisory council to the department: Dr. Edward G. Janeway, president; Dr. Horst Oertel, secretary; Dr. William T. Bull, Dr. Joseph Blake, Dr. W. Gilman Thompson, Dr. Simon Flexner, Dr. Frince A. Morrow, Dr. Daniel M. Stimson, Dr. Clinton L. Bagg, and Dr. Joshua Van Cott.

Officers of the Missouri Valley Medical Association.—The following officers were elected at the annual meeting of this organization, which was held in Omaha; recently: President, Dr. C. B. Hardin, of Kansas City, Mo.; first vice president, Dr. A. B. Somers, of Omaha, Neb.; second vice president, Dr. J. M. Bell, of St. Joseph, Mo.; treasurer, Dr. T. B. Lacey, of Council Bluffs, Ia; secretary, Dr. Charles Wood Fassett, of St. Joseph, Mo. The next meeting of the association will be held in St. Joseph, Mo., in March, 1909.

The Second Congress of the International Society of Surgery will be held in Brussels, September 21 to 25, 7908, under the presidency of Professor Vinzenz von Czerny, professor of surgery at Heidelberg University. Among the subjects selected for discussion are the following: The Nature and Treatment of Cancer, Diseases of the Liver and Bile Dutes, Methods of Inducing Anæsthesia, Etiology and Treatment of Hernia, and the Surgery of the Spinal Cord. There will be the usual exhibition of surgical instruments and appliances.

The Health of Pittsburgh.—During the week ending August 29, 1908, the following cases of transmissible
diseases were reported to the Bureau of Health: Chickenpox.
2 cases, 0 deaths; typhoid fever, 59 cases, 2 deaths; scarlet fever, 32 cases, 2 deaths; diphtheria, 10 cases, 1 death;
measles, 5 cases, 0 deaths: whooping cough, 3 cases, 0
deaths; pulmonary tuberculosis, 22 cases, 8 deaths. The
total deaths for the week numbered 141, in an estimated
population of 565,000, corresponding to an annual death
rate of 12.97 in 1,000 of population.

Tuberculosis Meeting in Philadelphia.—There will be a conference of men interested in the study of tuberculosis in Philadelphia on Monday, September 21st. The meeting is to be held under the auspices of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis and the Pennsylvania Society for the Prevention of Tuberculosis. Many of the delegates to the International Congress on Tuberculosis are expected to attend the conference. The entertainment committee, of which Dr. Charles H. Frazier is chairman, has arranged for a banquet to be given at the Bellevue-Stratford Hotel, at which the Governor of Pennsylvania will preside.

Society Meetings for the Coming Week:

Monday, September 21st.—Hartford. Conn., Medical Society.

Tuesday, September 22d.—New York Dermatological Society; Metropolitan Medical Society of New York City; Buffalo Academy of Medicine (Section in Obstetries and Gynæcology); New York Medical Union.

Thursday, September 22th.—Brooklyn Pathological So-

THURSDAY, September 24th.—Brooklyn Pathological Society; Brooklyn Society for Neurology; New York Celtic Medical Society.

Friday, September 25th.—Academy of Pathological Science, New York; New York Society of German Physicians. Saturday, September 26th.—West End Medical Society, New York.

Conference of Boards of Health.—The annual conference of State and provincial boards of health will be held in Washington, D. C., on September 25th and 26th. Among the topics to be discussed are: The Present Status of National and State Legislation relating to Public Health; a Law or Regulation Covering Country Slaughter Houses and State Meat Inspection; the Best Method of Providing County or District Health Officers; the Production of Vaccine and Antitoxine by the State; a Course of Instruction for Sanitarians and Sanitary Inspectors: the Welfare of Infants; Sanitary Inspection of States by a Representative of the U. S. Public Health Service: Regulations relating to the Quality of Milk and the Inspection of Dairies; Registration of Vital Statistics: Railway Sanitation; Present Management of Smallpox in Minnesota; Model Bill for the State Registration of Tuberculosis; Regulations relating to the Transportation of the Dead.

The New Haven County, Conn., Health Association held a meeting in New Haven on September 10th. Dr. J. C. P. Foster, of New Haven, president of the Connecticut State Commission on Tuberculosis, was present, and delivered the principal address of the afternoon. He spoke on the subject of tuberculosis, the duties of health officials in relation to the enforcement of laws relating to the disease, and the efforts being made by the association to prevent its spread. Officers to serve for the ensuing year were elected as follows: President, Mr. C. E. Hoadley, of New Haven; vice president, Mr. Hubert F. Potter, of North Haven; secretary and treasurer, Dr. E. A. Wilson, of Meriden.

The Mortality of Chicago.—During the week ending September 5, 1908, there were reported to the Department of Health of the City of Chicago 553 deaths from all causes, as compared with 584 for the previous week, and 574 for the corresponding period in 1907. The annual death rate in 1,000 of population was 13,31, as against a death rate of 14,20 in the corresponding period in 1907. The principal causes of death were: Apoplexy, 14 deaths; Bright's disease, 39 deaths; bronchitis, 7 deaths; consumption, 46 deaths; cancer, 32 deaths; diphtheria, 12 deaths: heart diseases, 38 deaths; intestinal diseases, 16 deaths; pneumonia, 35 deaths; scarlet fever, 4 deaths; suicide, 5 deaths; typhoid fever, 5 deaths; violence, other than suicide, 37 deaths; whooping cough, 4 deaths; all other causes, 121 deaths.

Infectious Diseases in New York:

We are indebted to the Bureau of Records of the Department of Health for the todoscing statement of new cases and deaths reported for the two weeks ending September 12, 1008.

New York State's Exhibit at the International Congress on Tuberculosis .-- A prominent place has been allotted to New York State in the new National Museum by the Committee on Exhibits of the International Congress on Tuberculosis. The work of preparing this exhibit has been conducted under the direction of Dr. H. D. Pease, director of the State Hygienic Laboratory. Among Pease, director or the State Tygienic Laboratory. Among the organizations and institutions that will contribute to the exhibit are the State Department of Health, the Charity Organization Society of the City of New York, the Department of Public Charities, New York City, the State Department of Agriculture, the State Charities Aid Association of Charities and Public Charities and Publ tion, the State Commission in Lunacy, the State Prison Commission, the official and voluntary organizations for the Commission, the official and voluntary organizations for the prevention of tuberculosis of Albany, Buffalo. Brooklyn. Saranac Lake, Syracuse, Rochester, Schenectady, Troy, Utica and Rome, Adirondack Cottage Sanatorium at Trudeau, State Hospital for Incipient Tuberculosis at Raybrook, Reception Hospital at Saranac Lake, Stony Wold Sanatorium at Lake Kushaqua, St. Gabriel's Home at St. Gabriel's, Loomis Sanatorium at Liherty, Montehore Home at Bedford, Senbrerge Hospital for Children at Exp. Rock. at Bedford, Seabreeze Hospital for Children at Far Rockaway, New York State Hospital for Crippled and Deformed Children at West Haverstraw, and numerous private institutions. There will also be two large exhibits dealing with the relation of milk to tuberculosis. One of these will be a model of a pasteurization plant, contributed by Mr. Nathan Straus, and the other a model depot for Meyer, chairman of the New York State Committee on the International Congress, in cooperation with the Hon. Seth Low, Dr. W. Law, Jr., Mr. V. Everett Macy, and the Hon. R. A. Pearson, State Commissioner of Agriculture. There will be an extensive exhibit of pathological specimens showing the lesions produced by tuberculosis in various tissues of the body, contributed to by all the larger hospitals and medical schools throughout the State. Apparatus that is used in the treatment of tuberculosis, such as sleeping bags, window tents, reclining couches, etc., will also be shown.

Charitable Bequests .- By the will of Charles Goodman, the Jewish Foster Home and Orphan Asylum, of Philadelphia, receives \$250, and the United Hebrew Charities Society of Philadelphia receives \$500.

By the will of Annie V. Jackson, the Women's Hospital, of Philadelphia, receives \$200.

By the will of Mrs. Mary H. Upham, of Malden, Mass., the New England Baptist Hospital, Boston, receives \$1,500.

By the will of Michael F. Callinan, who died recently at Bryn Mawr, the Bryn Mawr Hospital receives \$5,000; for the establishment of a Michael F. Callinan Free Bed the Bryn Mawr Hospital receives \$5,000; the St. Joseph's Home for Homeless Boys, Philadelphia, receives \$15,000; and the Sisters of St. Francis's Hospital, Quincy, Ill., receive \$500.

By the will of Mr. Robert W. Lord, who died recently in By the will of Mr. Robert W. Lord, who died recently in Marlboro, Mass, Boston institutions receive bequests as follows: Children's Hospital, \$2,000; Convalescent Home of the Children's Hospital, \$2,000; Industrial School for Crippled and Deformed Children, \$2,000; Perkins Institution and Massachusetts School for the Blind, \$1,000; Massachusetts Society for the Prevention of Cruelty to Children, \$1,000; John Howard Industrial Home, \$1,000, Young Men's Christian Union, \$2,000; Women's Charity Club Hospital, of Boston, \$600; Society for Helping Destitate Methers and Infants \$600; Young Men's Christian Association for use of Travelers' Aid department, \$600; trustees, St. Stephen's Settlement of Boston at Welcome

By the will of Senator William F. Vilas, the University of Wisconsin will receive an eventual endowment fund of \$30,000,000.

By the will of Mary Ann Kelly, the House of the Good Shepherd, of Philadelphia, and Saint Vincent's Home, of Philadelphia, receive \$300 each. The Little Sisters of the Poor and the Leper Colony are among the institutions to receive a proportionate share of \$1,200.

By the will of Henrietta W. Levick, the Home of the Merciful Saviour for Crippled Children of Philadelphia receives \$5,000 for the establishment of a free bed in memory of Mrs. Louisa G. Wilson. The Home of the Merciful Saviour and the Pennsylvania Society for the Prevention of Cruelty to Children are contingent legatees.

The Health of Philadelphia .- During the week ending August 29, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Typhoid fever, 102 cases, 5 deaths; scarlet fever, 16 cases, o deaths; chickenpox, I case, o deaths; diphtheria, 47 cases, 6 deaths; cerebrospinal meningitis, I case, o deaths; measles, Io cases, cereprospinal meningitis, I case, o deaths; measies, 10 cases, 2 deaths; whooping cough, 15 cases, 4 deaths; pulmonary tuberculosis, 83 cases, 37 deaths; pneumonia, 24 cases, 16 deaths; erysipelas, 2 cases, 0 deaths; puerperal fever, 3 cases, 2 deaths; cancer, 21 cases, 23 deaths; tetanus, 3 cases. I death; trachoma, 5 cases, o deaths. The following deaths were reported from other transmissible diseases: Tuberculosis, other than tuberculosis of the lungs, 9 deaths; diarrhea and enteritis, under two years of age, 65 deaths; dysentery, 2 deaths. The total deaths numbered 389, in an estimated population of 1,532-738, corresponding to an annual mortality of 13.20 in 1,000 of population. The total infant mortality was 132; under one year of age, 111; between one and two years of age, 21. There were 25 still births, 14 males and 11 females. The total precipitation was 3.08 inches. The average daily temperature was 64°.

During the weck ending September 5, 1908, the following cases of transmissible diseases were reported: Typhoid fever, 107 cases, 10 deaths; searlet fever, 17 cases, 2 deaths; smallpox, 1 case, 0 deaths; chickenpox, 2 cases, 0 deaths; diphtheria, 49 cases, 7 deaths; cerebrospinal meningitis, 2 cases, deaths; d I death; measles, 5 cases, I death; whooping cough, 12 cases, I death; pulmonary tuberculosis, III cases, 53 deaths; penumonia, 17 cases, 21 deaths; puerperal fever, I deaths; penumona, 17 cases, 21 deaths; tetanus, 3 cases, 2 deaths; trachoma, 2 cases, 10 deaths; tetanus, 3 cases, 2 deaths; trachoma, 2 cases, 0 deaths. The following deaths were reported from other transmissible diseases: Tuberculosis, other than that of the lungs, 5 deaths; diarrhea and enteritis, under two years of age, 50 deaths; dysentery, 1 death. The total deaths numbered 302, corresponding to an angual death, rate of 123 in 1000 of popularity of page 125. dysentery, I death. The total death infinite a 302 contests sponding to an annual death rate of 13.21 in 1,000 of population. The total infant mortality was 115; under one year of age, 80; between one and two years of age, 26. There were 34 will built a 2 in be and 11 female.

- The Use of Tuberculin as a Diagnostic Agent in Pulmonary Tuberculosis.-Barnes observes that the tuberculin test is at present necessary for the prompt diagnosis of many suspected cases of pulmonary tuberculosis, but it should be given only to patients who have symptoms or signs of tuberculosis. If given to other persons a positive reaction has no clinical value, because of the uncertainty as to the location of the lesions and the probability of healed lesions reacting. In the great majority of doubtful cases of pulmonary tuberculosis the subcutaneous test will give a correct diagnosis, which, if given judiciously in small initial doses, is safe; it should be given in Addison's disease with extreme caution or not at all. Of 225 hospitals in the United States having seventy-five beds or over, forty per cent. have used tuberculin in the diagnosis of pulmonary tuberculosis, 26.6 per cent. have used the subcutaneous method, 32.8 per cent. have used the ophthalmic method, 14.2 per cent. have used the cutaneous method. The accuracy of the ophthalmic and cutaneous tuberculin tests is yet to be proved, and cases reacting negatively to these tests should be tested by the subcutaneous method, unless the last named method is contraindicated. Cases suitable for the subcutaneous test should receive it in preference to the ophthalmic test, because of its greater safety. Of eighty-one medical colleges in the United States, 87.6 per cent. advise that the tuberculin test be given as a last resort in suspected cases of pulmonary tuberculosis, 76.5 per cent. have demonstrated the tuberculin test to their students, 62.9 per cent. have demonstrated the test by subcutaneous injecion, 70.3 per cent. have demonstrated the ophthalmic test, 37 per cent. have demonstrated the cutaneous test. All medical students should be thoroughly trained in the use of the three methods of applying the tuberculin test.

Incisions. Three Procedures for Entering the Pelvic
and Abdominal Cavities, By E. E. MONTGOMERY.

The Cerebral Centres for Taste and Smell, and the Uncinate Group of Fits.-Mills reports the case of a patient, who had suffered for about ten years from attacks of spells of unconsciousness, which were followed sometimes by convulsions. Examination for taste showed this sensation to be disarranged, while smell was retained. Autopsy of the brain showed a tumor on the left side of the brain, which hemisphere was much larger than the right. In a transverse section at the level of the upper part of the callosum the tumor filled the lateral ventricle above the thalamus, extending to the roof of the ventricle, and cutting off the anterior part of the ventricle above the head of the caudate nucleus from the posterior part of the ventricle. The tumor had the appearance of a glioma, was infiltrating and gelatinous in places. The upper part of the thalamus was entirely replaced by it. At a little lower level, where the anterior and posterior limbs of the internal capsule were well formed, the tumor invaded the thalamus, filled the front part of the posterior horn of the lateral ventricle, implicated the extreme anterior part of the median aspect of the occipital lobe, distorted the outer wall of the posterior horn of the lateral ventricle without extending into the temporal lobe, and involved the posterior part of the posterior limb of the internal capsule and a large part of the lenticula. At a level about one fourth of an inch lower the tumor extended to the anterior median surface of the occipital lobe, involved almost all of the lenticula, but did not extend into the white matter of the temporal lobe nor into the head of the caudatum, nor into the foot of the cerebral peduncle, which just below this level was beginning to form. At a level about one fourth of an inch still lower, where the cerebral peduncle was well formed, the tumor filled all of the anterior and median portions of the temporal lobe (uncinate and hippocampal convolutions) and the middle part of the lobe, but left the occipital lobe intact except in its extreme anterior part, and did not invade the lateral aspect of the temporal lobe or its subcortical white matter. tumor extended as a pointed process of brain tissue over the left cerebral peduncle, this being the only portion of the tumor appearing on the surface. The author's observations incline him to the view that the epigastric aura is only a part or at least a manifestation of the localized cerebral discharge, that it is due, in other words, to a discharge lesion which affects the cortical centres concerned with the representation or control of the sensory or motor or both sensory and motor side of the epileptic syndrome. Many facts would tend to indicate the truth of this view, among these being those which show the frequency of epigastric with gustatory and olfactory phenomena in reported cases. It is true that these gustatory and olfactory phenomena are often absent. It is, nevertheless, probable that sensory and motor centres concerned in some way with gastrointestinal interpretation have a more or less separate existence, and are situated in the same region of the brain as are the cortical centres for

taste and smell. The author concludes that much work remains to be done regarding the localization of functions in the inferior portion of the temporal lobe and the orbital surface of the frontal lobe. Cases like the one here first recorded, and the others to which reference has been made, are of value in the solution of the physiological problems concerned with these portions of the brain. The indications are all in favor, not only of the location in the uncinate region of the centres for smell and taste, but also for the representation in this region and its vicinity of the sensations produced by the activities of the abdominal and thoracic viscera.

5. Early Treatment of Some Superficial Cancers by Pure Radium Bromide Rather than Operation or X Rays .- Williams observes that the radiations from radium are uniform in quality and quantity and that thus this remedy has a great advantage over the x rays in efficiency and safety. The gamma rays from radium are useful in some cases for relieving pain; they have great penetrating When they are used as an analgesic the power. beta rays should be excluded or the patient may be burned, because the proportion of gamma rays is so much smaller than that of the beta rays that the exposure must be much longer when the gamma rays are used, to make them effective. The beta rays from radium are the useful rays in the treatment of rodent ulcers, epitheliomata, and other superficial diseases. They can be applied in the mouth and other cavities. Radium should be used early, and in suitable amount and strength; the treatment is painless and leaves the least scar; it does not produce as good results in cases in which an operation has first been done or scraping, caustic, or other irritating treatment has been used, or the x rays have been applied. Improvement follows the use of radium more promptly in many cases than the use of the x rays and the total duration of treatment by radium, though sometimes long, is much shorter than with the x rays. In some cases success has followed the use of radium where treatment by the x rays has failed. A surprisingly large proportion of external cancers, especially epitheliomata, have healed and remained healed for some years under treatment by radium, and the author's experience thus far indicates that for certain cases of external new growths it is a better remedy than those previously at our command. Recurrences follow all methods of treatment, and radium is no exception, but so far as present experience goes this is unusual, and they have yielded to further treatment by radium. The disadvantage of radium is its cost to the physician.

To. The Vaginal, the Vertical Abdominal, and Pfannenstiel Incisions.—Montgomery states that the advantages of the vaginal route are: Drainage is from the most dependent portion of the peritoneal cavity; in a fair proportion of cases it permits the cure of the patient by a less radical procedure; the convalescence of the patient, even after a hysterectomy, is more rapid and attended with less discomfort than is associated with the same procedure through the abdomen; the restoration to health is expedited, and the patient is spared such sequelæ as ventral hernia and ventral adhesions; in many cases it permits the peritonæum to be closed over the vagina, the stumps of the broad ligaments

being brought out so that all ligatures and raw surfaces are excluded from the peritoneal cavity, leaving opportunity for the formation of adhesions. The route has the following disadvantages: It must be, in many cases, a blind one, as extensive adhesions must be separated by touch; injuries to the intestines or previously existing intestinal sinuses are likely to be overlooked, fæcal fistula may form and imperil life, or destroy the health and comfort of the patient; extensive adhesions of the intestines are unrecognized, or form subsequent to the operation, and lead to obstruction and consequent disaster. The initial adhesion need only be a small one on the outer margin of the coil of gut to become a serious menace. With this adhesion as a fixed point, peristalsis may lead to twisting of the loop and result in obstruction. An obstruction may exist which other peristaltic movements may undo, producing symptoms of intermittent obstruction, or the torsion may become aggravated. Of the abdominal route the author remarks that the incision in the median line is without doubt the procedure capable of the widest application. It affords ready access to the pelvis, and when required may be so extended as to permit the inspection and manipulation of the contents of the entire abdominal cavity. Observation discloses, however, that the patient suffers greater discomfort during convalescence than is experienced by the patient who has suffered a similar or greater deprivation of organs by the vaginal route. Nature's barriers are necessarily broken down, and both peritonæum and incision are exposed to infection. The situation of the wound is not the most favorable for drainage, as a portion of the cavity, generally that which has been subjected to the greatest injury, is below the most dependent portion of the incision. Drainage, consequently, must be against gravity. In acute infections, this defective drainage frequently compels the operator, in order to be safe, to do more than he would feel obliged to do had the vaginal route been substituted. The advantages of Pfannenstiel's method are thus summarized: It permits a larger exposure of the field for a comparatively small incision; as the interior and middle lines of suture closing the wound are at right angles to each other, the probabilities of subsequent hernia are lessened; as the incision through the skin is, under ordinary circumstances, within the portion covered by the pubic hair, with its regrowth the site of the scar is completely obscured. Its disadvantages are as follows: It is of limited application and consequently unsuitable for the removal of fibroid tumors of any size; the necessarily large opening of the cellular tissue makes it undesirable for the treatment of pus collections within the pelvis, as it is difficult to preserve the wound tissues from infection.

2. Remarks on Acute Intestinal Obstruction with Especial Reference to Intussusception .- I'eterson says that the cardinal symptoms of acute obstruction are pain, vomiting, and persistent constipation. The general picture is one of shock, accompanied by marked restlessness. The face is pinched and anxious, and the eyes are sunken. There is more or less cyanosis, due to impeded respiration. Respiration is accelerated and shallow, and even the tone of the voice may be altered. The skin is clammy, the extremities cold, and the temperature is often subnormal. When the temperature is elevated, it is due either to the absorption of the toxines or to the presence of peritonitis. Thirst is extreme, and the tongue is dry. Hiccough is often distressing. The pulse is small, weak, and rapid. The urine is scanty. high colored, or may be suppressed; usually it contains an excess of indican, indicanuria being especially marked when the seat of the obstruction is high. Abdominal tympany usually develops late and varies greatly, according to the nature and site of the obstruction. The lower the occlusion in the intestinal tract, the more pronounced is this symptom; when the trouble is high up, tympany is either slight or absent altogether. The presence and constancy of these symptoms will depend, of course. upon the location of the occlusion and upon the degree of obstruction and strangulation. Of the treatment the author remarks that as a general rule, the distention of the colon by hydrostatic pressure, the insufflation of the bowel with gas, abdominal taxis. massage, etc., are not only unscientific and useless. but in some instances are positively dangerous. Puncture of the intestine through the abdominal wall for the relief of tympany is mentioned for condemnation only. Inversion and violent shaking of the patient are apt to do more harm than good. The administration of shot or metallic mercury, employed in olden times, is mentioned merely as a curiosity in the way of treatment. Do not give purgatives, as they increase the pain and vomiting, and add to the risk of gangrene, perforation, and peritonitis. They can accomplish no possible good. Use opium very cautiously, for this drug so masks the symptoms and obscures the general picture, that it leads too often to fatal delay in the employment of radical treatment. Do not employ stomach lavage, except for diagnostic purposes or until a diagnosis has been settled, for this measure has almost the same sedative effect as opium, and is apt to give the attending physician a feeling of false security. After a diagnosis is determined, lavage of the stomach and colon should be carried out, for it lessens the vomiting, the pain, and the absorption of toxines. and also renders safer the administration of an anæsthetic. Generally speaking, a prompt laparotomy, quickly performed, is by all odds the safest, the simplest, and the surest method of accomplishing a cure. The operation itself, if performed early, is not more difficult or dangerous than laparotomy for the other intraabdominal lesions. A general anæsthetic is contraindicated in cases seen late, where shock and collapse are pronounced, for in such a state, a narcotized patient is in danger of drowning

in his own vomitus. Here the operation should be performed under local anæsthesia, with, perhaps, the addition of morphine and hyoscine. There is no single measure so useful in combating the shock of intestinal obstruction cases in general as the intravenous infusion of normal salt solution. It strengthens the heart, allays the extreme thirst, and stimulates the urinary flow. Of drugs, the most valuable is sparteine sulphate, administered hypodermically; it slows and strengthens the heart and has decided diuretic action. After an obstruction has been relieved there are one or two practical points which will add greatly to the comfort of the patient. The stomach should be washed out immediately, and as often thereafter as indicated. Eserine salicylate should be started at once. This drug will aid in reestablishing normal peristalsis and by its action will lesson or prevent tympanites. Hot saline solution should be given by rectum, at frequent intervals, or, if necessary, it can be given continuously. The bowels should be moved by enema when they do not act spontaneously, rather than by drugs by

3. Abnormal Motility of the Stomach a Valuable Factor in the Diagnosis of Gastric Lesions. -Barker observes that the loss of gastric motility characterized by long continued stagnation of food in the stomach, and the partial or complete absence of mucus in the gastric contents, are characteristic of cancer, and when such conditions prevail careful search for the Oppler-Boas bacillus should be made. If this is found the diagnosis of cancer is positive; if it is not found the patient should not be allowed to pass into that stage of the disease in which operative measures are futile, by waiting for this more positive element in the diagnosis before exploratory measures are taken. A large accumulation of mucus in the stomach is one of the important elements in the diagnosis of chronic gastritis. This is due, in a large degree, to faulty contact between the ingested materials and the nerve centres in the stomach walls causing gastric immotility, which, in turn, prevents the escape of the accumulated mucus into the intestines. The vicious circle being thus formed is broken up in certain cases by ·long continued lavage; hence one of the beneficial effects of this treatment in chronic gastritis. A prominent factor in the diagnosis of gastric ulcer is the exaggerated motility of the gastric walls. This is characterized by the absence of any portion of a test meal in the stomach a comparatively short time after its ingestion. Mucus is also almost or entirely absent from the stomach in this condition, being digested as quickly as deposited in the stomach by the ever present overacid secretion, and being expelled from the stomach quickly because of the exaggerated motility of the gastric walls.

1. Appendicular Inflammation.-Moullin states that the actual exciting cause of appendicular inflammation is always and everywhere septic organisms which always invade the appendix from the mucous surface. Stercoliths, foreign bodies, old adhesions, strictures, etc., help by favoring the growth. and retention of the septic organisms. Fatigue, exhaustion, and cold help by lowering the resistance of the patient's tissues. It is the position of the appendix lying covered with peritonæum in the general peritoneal cavity that makes the consequences so serious. The ideal in operating is to prevent these consequences. The sharp attack of pain is always preceded by a premonitory stage of general abdominal discomfort and pain, with nausea. In other words, septic decomposition has been going on in the intestine. There is always the possibility during this initial stage of clearing out the septic organisms from the appendix. But once the acute iliac pain has begun medical treatment is hopeless. Complete abstinence from food for twenty-four hours should be insisted upon, and the patient should be confined to bed. Calomel is the only intestinal antiseptic of any value. The sudden outbreak of acute iliac pain means that the parietal peritonæum is involved. The appendix itself is devoid of ordinary sensation and ordinary sensory nerves. But the parietal peritonæum is

exquisitely sensitive, and where there is the least degree of inflammation, its sensitiveness is increased tenfold. The severity and persistence of the pain are of the greatest importance. If, without opium, it subsides in a few hours, and no collapse or muscular rigidity appears, the inflammation is probably slight. But if the severity of the pain continues, and particularly if the area over which it is felt shows a tendency to enlarge, then early operation will probably be required. Gradual alleviation of the pain suggests that the inflammation is becoming localized. But rapid disappearance of the pain at the end of twenty-four or forty-eight hours, especially in a young subject, is a most disquieting symptom. It often means that the patient is becoming poisoned; that the appendix is becoming gangrenous; that a dangerous degree of septic absorption has set in; and that the pain is not felt because the patient is fast losing the capacity of feeling it. In many instances the skin over the right iliac fossa is exceedingly sensitive—"hyperalgesia" is a better term than "hyperæsthesia." The region is quite defined and bears no relation to the anatomical position of the appendix. Affections of the gallbladder and duodenum also have their distinctive areas of hyperalgesia, but they always lie above the umbilicus. This cutaneous hyperalgesia has nothing to do with the peritonæum. It is merely the expression of the irritable state of the nerve centre, which receives afferent impulses equally from the appendix and the skin over the iliac fossa. Deep tenderness is entirely different and is directly proportionate, both as regards extent and intensity, to the state of irritation of the parietal peritonæum beneath the spot at which the pressure is applied. The demonstration of McBurney's point is of the greatest value, as the point of greatest tenderness is nearly always over the base of the appendix. A single blood examination is not of great value, unless the number of leucocytes is excessive. Successive examinations at intervals of a few hours are of much greater value. A progressive increase in the number of the leucocytes calls for immediate operation. The pulse rate is the most valuable indication in appendicitis; an increasing pulse rate is an absolute command for operation. The temperature, taken by itself, is seldom conclusive. Even when there is a large abscess, the temperature may rise but little above the normal. A sudden rise of temperature during apparent convalescence nearly always means a relapse with extension of suppuration, demanding immediate evacuation. A rapid fall of temperature, especially with a rising pulse rate, means the beginning of the hopeless stage of general septic poison-There is no single symptom which is constantly present. But one single important symptom, if it is definitely getting worse, is enough to justify immediate operation. The earliest operations are the most successful, not only as regards immediate mortality, but as regards rapidity of recovery.

4. Anatomy of Herniæ.-Carmichael's conclusions are as follows: 1. In early childhood clinapparently normal children, shows that between fifty and events five per cent present thickening due to incomplete closure of the funicular process. 2. The

anatomical conditions present in operated cases support the view of a congenital origin, as shown by the relation of the sac to its coverings, and its presence in spite of a narrow canal and a small external abdominal ring. 3. The histological and naked eye appearances of the sac in most cases do not afford reliable evidence of its congenital origin or otherwise, although a markedly thickened sac, if small, is suggestive of the embryonic condition.

9. Pulmonary Tuberculosis.-Niven, in discussing the notification of pulmonary tuberculosis, lays down the following fundamental conclusions: 1. Children very rarely have tuberculosis at birth. The proportion affected probably increases continuously within the first few years of life. 2. Some cause of infection present in early childhood becomes much less prominent after the first few years. 3. With the advent of adolescence, when the strain of work is introduced, the numbers affected again rapidly increase. 4. The proportion attacked increases up to a fairly advanced period of life. The diminution in the death rate in advanced years is due to the cessation of employment. 5. În some manner or other infection is conveyed in houses, workshops, etc., in which a consumptive is present. 6. It is not true that tuberculosis is a disease contracted mainly in infancy from milk, and remaining latent to become active later on. When children, who have had tuberculosis and recovered, develop the disease in later life, it is probably due to reinfection. 7. The disease is of recent origin in most cases. 8. Many circumstances, such as poor nutrition, bad habits, overcrowding, etc., may condition the attack. But the infective element is always a requisite. 9. Repeated and prolonged exposures to infection are required in order that healthy persons may contract the disease. 10. The most common latent period is about one year. 11. By far the most common vehicle of infection is infectious dust derived from tuberculous sputum.

Acetate, By G. DIESSELHORST.
II. Concerning the Dehiscences of the Maxillary Antrum,
By Kanasugi.

2. Influence Exerted upon Malignant Tumors by Atoxyl and Foreign Albumin.-Sticker declares that atoxyl does not attack the tumor cells directly but exerts a sort of catalytic action by stimulation of the hæmatopoietic system, especially of the bone marrow, so as to produce an increase of material hostile to the tumor. The removal of the destroyed tumor, when the destruction has been brought about by the injection of blood, is further carried out by the neutrophile leucocytes, perhaps with the aid of the proteolytic ferments. The treatment with injections of blood is to be considered to belong to the specific autofermentative methods, the atoxyl treatment to the heterofermentative.

3. Injections of Placental Blood in Carcinoma .- Falk finds that the placental serum is not to be considered a means for removing carcinoma to be compared with trypsin, papajotin, or the liver

5. Obesity.—Brieger treats obesity by a combination of a modified Karell's treatment with hydrotherapy and gentle mechanotherapy which he not only considers efficient in reducing the corpulence but also in strengthening the heart and nervous system.

8. Therapy of Hypertrophy of the Prostate. -Casper has tried the x ray treatment and abandoned it as useless. Aseptic catheterization and suprapubic prostatectomy remain the standard meth-

ods of treatment.

10. Excretion of Lead after the Internal Use of Lead Acetate.-Diesselhorst found lead in the urine and perspiration even after small doses. He did not find an increased excretion in the perspiration in the light bath as distinguished from other means of diaphoresis.

11. Myopia and its Prevention (Concluded), By BEST

12. Needs of Reform of the Penal Code from a Psychiatric Point of View (Concluded), By Craver 13. Obiting of Point of View (Concluded), 13. Obituary of Professor Herman Snellen,

By Eversbusch. I. Reduction of Obesity.-Moritz usually gives the patient two litres of milk a day, divided into five portions. The patient drinks one half litre at 7:30 a. m., one fourth litre at 10 o'clock, one half litre at 1, one half litre at 4, and one half litre at 7. This quantity may be increased or diminished according to the behavior of the patient, who must be seen every other day. If the loss in weight is too rapid the quantity of milk is increased, if too slow it is decreased. Cooked milk is preferred, but with a good source of milk and in adults raw milk may be used. One or another portion may be of sour milk. The milk may be drunk either cold or warm, according to the taste of the patient. If the patient is still thirsty after drinking the milk one half to three quarters litre of water may be given, or may be mixed with the milk. Nothing else is given in addition to the milk, with the possible exception of the water. He finds this to be the simplest, most convenient, and cheapest known treatment of this condition. It enables the physician most easily to individualize in the treatment of his patients, and makes the least call upon the aptitude of the patient to carry out his directions. Severe hunger does not occur, in spite of the small amount of nutrition, and thirst is absent. The milk treatment is particularly indicated in the presence of complications on the part of the heart or kidneys.

2. Collapse Induration of the Apex of the Right Lung.—Blümel says that there is a typical disease of the lungs in individuals with chronic interference with nasal respiration, first described as such by Kroenig, that consists of a fibrous induration with collapse of the apex of the right lung, and can be distinguished from tuberculosis by the history, clincal appearance, bacteriology, and the test with tuberculin. The diseased condition is due to the inhalation of dust. It is preceded by catarrh of the pharynx, larynx, trachea, and bronchi produced in consequence of the exclusion of the nose as a protection to the respiratory apparatus. The apices of the lungs are involved before the other parts, the right apex before the left, because of anatomical conditions. The disease is a form of chronic, fibrous, interstitial bronchitis.

3. Retrograde Lymph Movement.-Hart asserts the retrograde lymph movement from the thoracic duct into the lymph gland in the angulus venosus may, under certain conditions, produce not only tuberculosis of the tracheobronchial glands but of the cervical as well. Therefore tuberculosis of the lower cervical glands with or without coincident pulmonary tuberculosis is not a proof of an infection in the region of the commencement of the cervical lymph tract, as it may come by way of the lungs and the bronchial lymphatic glands, or from the thoracic duct.

4. Treatment of Ophthalmia Neonatorum.-Gilbert recommends instead of confining the treatment to the usual frequent cleansing of the eyes with slightly antiseptic solutions to add to these the washing out of the eyes personally every two hours. He does not favor its adoption as the sole means of treatment.

11. Myopia and Its Prevention.-Best declares that the quintessence of the practical part of his long paper is this: Only near work, reading, writing, and partly hand work, makes the growing eves of our children near sighted. Much more important than the care for good light is the limitation of the reading and writing, the abolition of the German alphabet, and the spread of this knowledge among all circles of people.

GLASCOW MEDICAL JOURNAL.

Jugust 1908

Congress of the Extremities after Pheumonia, with Notes of Two Illustrative Cases,

An Experimental Investigation into the Function of the Thynnis Gland, By ALEXANDER MACLENNAN Case of Chorion Epithelioma,

Case of Chorion Epithenoma,
By George Balfour Marshall.
Case of Rare Pelvic Tumor reschald of Four Years,
By Thomas Kay

- 1. Gangrene of the Extremities after Pneumonia.—McGregor remarks that the evidence of varieties of causes of gangrene is not so complete in pneumonia as in typhoid fever, on account of the paucity of cases and observations, but the similarity of the lesions in the two diseases is very marked. The following factors in pneumonia may determine gangrene of the extremities: 1. The blood containing pneumococci, probably in all cases, and with a marked agglutinating power which increases up to the crisis and then gradually diminishes. 2. The weakness due to the acute fever, and in particular the cardiac asthenia, which is most marked immediately after the crisis. 3. The occurrence of pneumococcic endocarditis, even in the earlier stages of pneumonia, sometimes resulting in the formation of clots or vegetations, which, passing into the arterial circulation, become emboli. 4. The invasion of the veins by pneumococci causing phlebitis and thrombosis, sometimes followed by pulmonary embolism. 5. A probable similar invasion of the intima of the arteries resulting in arterial thrombosis. 6. Thrombosis of arteries following embolism, where the clot formation extends to some distance and shuts off the collateral circulation.
- 2. Experimental Investigation into the Function of the Thymus Gland.-MacLennan observes that the thymus may be a lymphatic gland, but it is so specialized as to be virtually something more; it is one of the series of glands which by an internal secretion regulate the various functions of the body. It is really an accessory one, for its function can be taken up by others. It is to be remarked that simultaneous extirpation of the spleen and thymus invariably ends in death. One would therefore infer that the spleen can carry on along with its other manifold functions those of the temporary thymus. Extirpation of the thymus does not give rise to hypertrophy of adenoid tissue elsewhere. The function of the gland is temporary, for as growth advances the gland atrophies, though in man the gland never quite disappears till after puberty. There are cases on record, however, where there has been no thymus. The thymus and the thyreoid are closely associated developmentally, anatomically, physiologically, and pathologically. In two extirpations of the gland in the human subject he has found the thymus continuous with the left lobe of the thyreoid. The results of ex-periments have shown that the thymus is un-necessary to the economy when the thyreoid is gone, and when the thymus is removed less thyreoid suffices. The importance of this relationship is apparent in certain diseases. Thus, there is a type of Graves's disease where extirpation of the thyreoid is followed by sudden death, and on post mortem examination the thymus is found enlarged. An enlarged thymus is credited, certainly rightly in some cases, with being the cause of death in the so called status lymphaticus, and after removal of the thyreoid the enlarged thymus gives rise to the same conditions as produce the so called thymus death. Therfore, in such cases, where thyreoidectomy was decided necessary in Graves's disease, the writer recommends that the thymus be first sought for, and if enlarged be removed as a preliminary to the thyreoidectomy.

What is the Most Effective Organization of the American National Red Cross for War, and What Should be its Relations to the Medical Departments of the Army and Navy? By Henky I. RAYMOND. The Medical Service of the United States Marine Corps,

By Frederick L. Benton.
Observations upon Treponema Pertenuis (Casteilani) of Yaws and the Experimental Production of the Disease in Monkeys, Part II, By Captain Percy M. Ashburn and Captain Charles F. Craig.

Treponema Pertenuis in Yaws.-Ashburn and Craig believe, as a result of their observations, both clinical and experimental, that Treponema pertenuis is the cause of yaws, and is constantly present in the setum of yaws lesions, and can be demonstrated in sections of yaws papillomata by the Levaditi method. The inoculation of the serum from human yaws lesions containing Treponema pertenuis causes yaws in monkeys and the organisms can be easily demonstrated in the lesions of the infected animals. The variations in the morphology are explainable by the deformities produced during the preparation of the serum for examination. Treponema pertenuis and Treponema pallidum can be distinguished by the results obtained from the inoculation of monkeys. The length of the period of incubation in Cynomolgous philippinensis (Geoffroy) is approximately twenty days, while the duration of the inoculated disease in this species of monkey varies from twenty-one to eighty-four days. Yaws and syphilis are distinct diseases.

Proceedings of Societies.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Meeting of April 20, 1908.

The President, Dr. ROBERT T. MORRIS, in the Chair.

Various Clinical Types of Acute Dilatation of the Stomach.-Dr. ROBERT COLEMAN KEMP read this paper. He expressed the opinion that acute dilatation was of quite common occurrence, especially in its milder forms. In some instances the attacks were primary, resulting from dietetic indigestion; in others they were found in connection with different diseases and caused a modification or apparent exacerbation of the original affection. His object in presenting this paper was to impress upon his hearers the necessity of careful and frequent examination of the abdomen in all cases and to call attention to various clinical symptoms in the production of which such acute dilatation was often the exciting cause. The paper was not only clinical, but also experimental, and it included a study of the effects of artificial distention of the stomach, some physiological experiments on animals, and an investigation, upon the cadaver, of the mechanics of acute dilatation of the stomach. There were four anatomical types: I. Acute dilatation of the stomach alone. 2. Acute dilatation of the stomach supervening upon an existing chronic dilatation, due to stenosis of the pylorus. 3. Acute dilatation of the stomach

and duodenum-the most fatal type. 4. Acute dilatation of the stomach and intestines—a mixed type. The last of these was frequently present in the acute infectious diseases, such as pneumonia and typhoid fever, and in the acute distention of typhoid, with active hæmorrhage, lavage would often prove of service. If the fatal cases were followed up into the post mortem room, it would astonish many to find how frequently there was a marked distention of the stomach and intestines, though during life this might not have been thought to have any bearing upon the fatal issue. In speaking of certain anatomical features of the stomach and duodenum, Dr. Kemp said that, as the result of experiments made by himself and Dr. A. T. Weston, it seemed demonstrable that there was a valvular action of the cardiac, even in the cadaver. This action was probably variable to a greater or lesser degree in the living subject. In experiments on dogs by Kelling and Braun, it had been found that, after gastrostomy, it was impossible to produce acute dilatation of the stomach when the animals had recovered from the anæsthetic, since, when a certain degree of inflation was reached, vomiting was excited and the stomach was emptied. During narcosis, however, the stomach could be distended to nearly the bursting point without the escape of air from the œsophagus. After complete paralysis of the stomach such escape was prevented, evidently by some valvular action of the cardiac. The transverse portion of the duodenum was held very firmly in place near its termination by a band of fibrous tissue descending from the left crus of the diaphragm, and the Kemp and Weston experiments went to show that this fibrous attachment, which had not hitherto been considered in the mechanics of the gastroduodenal type of acute distention, was an important factor in the production of obstruction.

Having referred to the nerve supply of the stomach and its importance in connection with the subject, the speaker proceeded to classify the various clinical types of acute gastric dilatation, or, possibly it might be said more correctly, the various clinical symptoms in the production of which such acute dilatation was a factor. In infants and young children convulsions from overloading the stomach were not infrequently observed. In a child of two years. suffering in this way, he had noted acute dilatation of the stomach, which extended two fingerbreadths below the umbilicus. After severe vomiting the convulsions ceased, and the stomach returned to its normal size. Mangelsdorf, who had carried on very extensive researches in epilepsy, had demonstrated acute dilatation of the stomach during the convulsive seizure, and believed it to be a factor in the production of the attack. Other nervous affections in connection with which acute dilatation had been observed were migraine, tetany, and chorea. Dr. Kemp had seen in the second of two attacks of tachycardia a young woman of twenty-one who had mitral stenosis and aortic regurgitation, but with excellent compensation. Both attacks followed marked indiscretions in diet, and in the one in which he saw her there was pronounced gastric dilatation, which disappeared after emesis from warm water.

Having related a case of pseudoangina pectoris,

produced by acute dilatation of the stomach, which had come under his observation, Dr. Kemp said that in order to study the effects of acute dilatation on the pulse, respiration, and blood pressure, Dr. Satterthwaite and himself had observed these conditions in two normal subjects, a physician and a trained nurse, and in a case of gastroptosis. Each stomach was distended by means of carbon dioxide gas generated from tartaric acid and sodium bicarbonate, and the effects, as shown by the sphygmomanometer and otherwise, carefully noted. Coincident with the rapid gastric dilatation there were marked increase in the rapidity of the pulse and respiration, changes in the character of the pulse, and fall of blood pressure. The stomach of the physician, from whom the most reliable data were secured, extended downward to one fingerbreadth below the umbilicus. He stated that he experienced much discomfort, suffering from pain beneath the sternum and over the abdomen and a sense of flushing of the face and suffocation, accompanied with nausea. The stomach was then aspirated, and these sensations disappeared. The chart of the recorded efforts showed that the pulse had risen from 72 to 135, becoming irregular in force and with some intermission in the beats. The respirations had increased from 18 to 24, and the blood pressure had fallen from 135 to 120. In a series of experiments in artificial acute dilatation of the stomach made by Dr. Kemp on dogs, of which he gave the details, the results corresponded with those observed by Dr. Satterthwaite and himself in

the clinical experiments mentioned. The speaker then reported a fatal case of gastrointestinal distention complicating typhoid fever, in which the pulse became rapid and feeble and the respiration shallow and gasping, with marked cyanosis, and in which death occurred with cardiac dilatation, resulting apparently from pressure interference alone. Such distention he believed to be one of the direct causes of death in these cases. In typhoid the tympanites seemed to be generally regarded as chiefly intestinal, while little attention was paid to the condition of the stomach. When abdominal distention occurred, it was due either to the systemic infection or to dietetic errors, and in either case a selective action on the intestines appeared absurd. The mixed type of acute dilatation (the gastrointestinal) was quite common. Several fatal cases of the gastroduodenal type had been reported, but they were comparatively rare. There were many instances in which cardiorespiratory symptoms occurred which might be suggestive of some pulmonary complication, where examination would show the cause to be acute distention of both stomach and intestines. Postural treatment (raising the head of the bed on blocks) would demonstrate that the condition was due chiefly to pressure, just as in some of the experiments described. By this means in one case the tympanitic area in the thorax was lessened by four inches, while the pulse fell from 140 to 120 and the respiration from 40 to 20, showing the influence of pressure alone. In pneumonia the extroduodenal type of acute dilatation, with characteristic symptoms, had proved fatal in a num-Let of instances, the condition being evidently due to involvement of the vagi during the course of a pneumonia at the base of the lung. Here the most frequent type, however, was the mixed, or gastro-intestinal, and the toxines of pneumonia and improper feeding were the chief causes of its occurrence. In many cases the symptoms suggested an extension of the pulmonary disease, or even cardiac complications, but a careful examination would show distention to be the causative factor, and the postural treatment would, by removing pressure, temporarily relieve the acute symptoms.

A case of acute dilatation of the stomach was narrated in which coprostasis was the chief symptom associated with this. The patient, a man of fifty-five, had indulged very heartily in bananas and milk, and the distention promptly followed. For ten days there was no movement of the bowels, and a movement was secured only after two days of active treatment, making in all an obstipation of twelve days' duration. On the tenth day, when marked gastric dilatation was still present, he was first seen by Dr. Kemp. After lavage, the stomach retracted to the normal, and the obstinate constipation was finally overcome by enteroclysis and the administration of calomel and various salines through the stomach tube.

The next case he reported was one of acute dilatation of the stomach supervening upon a chronic dilatation due to stenosis, occurring in an actress, forty-five years of age, in whom the cause of the pyloric stenosis was a partially healed ulcer. Here also the acute dilatation resulted from a dietary indiscretion. Having stated that, while acute dilatation might occur at any age (his youngest patient being two years of age and his oldest seventy-five), three fourths of the cases were probably met with during adolescence or early adult life, and in the matter of sex the cases were about equally divided, he proceeded to give Conner's classification of the cases into groups. In speaking of postoperative dilatation, he said that this occurred more frequently after chloroform than after ether. Manipulation of the viscera, shock, uræmia, or sepsis might be a factor in its production. Conner had stated that in no instance did it follow an operation on the stomach itself, but in one of Dr. Kemp's cases it occurred after a gastroenterostomy. In this instance he believed that the diet was chiefly responsible, though the anæsthetic and the handling of the stomach might have been contributory factors. The so called prolonged postnarcotic vomiting and the supposed vicious circle were probably quite frequently due to some degree of acute dilatation of the stomach.

The characteristic symptoms of acute gastric dilatation in some cases were sudden abdominal distention, pain, tenderness, excessive vomiting, constipation, thirst, scanty urine, and rapid collapse. In the gastric and gastroduodenal types the distention was not uniform, but chiefly filled the left half and lower part of the abdomen, while the right hypochondrium appeared to be flattened. If the swelling subsided after thorough lavage, it was proof that the difficulty was confined to the stomach or to the stomach and duodenum; while, if the distention remained after lavage it showed that the intestines were also involved. Splashing sounds (succussion) and the

sense of fluctuation were aids to the diagnosis, but they were not always present, and particularly in the early stages, when there was but little fluid in the stomach. Percussion would generally show the resonance increased, but this would be interfered with when there was much fluid, being most important when the splash and fluctuation were absent. Peristaltic waves of contraction were very seldom The prognosis in the recorded cases was bad. We had here one of the most formidable conditions in medicine or surgery, the death rate in this class of cases being seventy-two per cent. Cessation of vomiting was not always a favorable sign, as it might occur, with increasing abdominal distention, just before death. In the future, however, the speaker believed, in consequence of a more careful study of this affection, including its earlier recognition, the percentage of fatalities would be very materially diminished.

The next two sections of the paper were devoted to the morbid anatomy of acute dilatation and to an elaborate study of the mechanism of the production of the condition. In the concluding portions the diagnosis, prophylaxis, and treatment were considered. In the way of prevention, rapidity in operating and the minimum amount of anæsthesia, as well as of manipulation of viscera, were important, and after operations care in the kind of feeding and avoidance of pushing the food in too large quantities were necessary. In typhoid fever, pneumonia, and other infectious diseases, the abolition of milk diet and the substitution of broths and strained soups of various kinds, such as barley, rice, and gruels, was a step in the right direction. If a patient had had one attack, the condition of the gastric secretion should be investigated, irregularities should be corrected, and a course of proper diet should be instituted. In every case of acute dilatation of the stomach the stomach should immediately be evacuated by lavage, and this should generally be repeated in two or three hours, and thereafter at intervals of from four to six hours during the first twenty-four hours. In severe cases it might be necessary to repeat the lavage even more frequently, and to continue its use for some days. All feeding should be by the rectum for several days, or until the symptoms had disappeared, and if there was severe thirst, saline enemata or even hypodermoclysis might be employed. Rectal irrigation was of value if intestinal distention was present, and it was also useful in promoting bowel action. peristaltic action of the stomach and intestine should be started up as soon as possible, and it was Dr. Kemp's practice, unless contraindicating circumstances were present, after washing out the stomach with water in which two ounces of milk of magnesia had been dissolved, to give from three to five grains of calcmel through the stomach tube before removal, and a saline four to six hours later by the same method. In his case with coprostasis it was interesting to note that the addition of electricity to the continuous enteroclysis first produced a movement of the bowels. Drugs which were of service were strychnine and belladonna (or atropine hypodermically). Exercise had been recommended, but it was depressing. The therapeutic measure next in importance to lavage was postural treatment, the method employed depending upon the anatomical type of the dilatation and the character of the case. In the gastrointestinal type the semi-oblique or nearly sitting position was required, this being secured by blocking up the head of the bed. The second method which had been suggested was elevation of the foot of the bed, the object being to relieve pressure upon the duodenum. The objection to this was the danger of pressure on the heart and lungs. Third, in the gastroduodenal type the lateral position (either right or left) had relieved the symptoms. Fourth, in this type the preferable method was the abdominal position (the patient lying on the belly). Operative procedures had not proved successful in this affection.

Pepsin Determination. — Dr. MAX EINHORN presented an apparatus devised by himself which simplified the Jacoby-Solms method of pepsin determination.

The Local and Surgical Treatment of Chronic Diarrhœa. — This paper, by Dr. Samuel G. Gant, has been published. (See New York Medical Journal, August 15, 1908, pp. 289 et seq.) In connection with the paper, Dr. Gant presented eight patients upon whom he had operated, in most of the cases for ulcerative colitis. The operations done in different instances were appendicostomy, colostomy, cæcostomy, and the new Gant operation. Some of them were performed as long as two years ago, and the patients were now in excellent health, although in one case a hernia had resulted from the operation (an appendicostomy). In some cases the operation had been done only very recently, and the patients, not yet cured, had all gained in weight and otherwise showed marked improvement. The seventh case was one of gonorrhœal ulcerative proctitis, and the eighth one of carcinoma. In the latter instance Dr. Gant contemplated a radical operation, the resection of a considerable portion of the bowel.

Four Cases of Perforating Ulcer of the Alimentary Canal.-Dr. H. BEECKMAN DELATOUR read this paper. A man, thirty-three years old, thirty-six hours after the onset of severe abdominal pain, attended with chills and some febrile reaction, had a large swelling in the epigastrium. After an incision above the umbilicus and the separation of adhesions below the stomach, there was an escape of pus, which, however, did not soil the peritonæum. Zinc gauze was packed into the opening, the peritonæum sutured over this, and the abdomen closed without drainage. The patient was then placed on the right side and an incision made along the twelfth rib, the dissection being carried up until the abscess cavity was reached from behind. After a large quantity of thin, fœtid pus had been evacuated, the end of the piece of gauze introduced from in front was withdrawn, and a rubber drainage tube inserted. Subsequently, when milk had been taken by the mouth, it would immediately appear at the drainage tube, indicating a perforation at the seat of an ulcer on the posterior wall of the stomach. Later the wound healed and there was no further trouble. The second case, in a man, fifty-six years of age, was one of perforation of the duodenum. On operation, an opening about a quarter of an inch in diameter was found on the inferior aspect

of the first portion of the duodenum, and there was necrosis of some of the adjacent bowel wall. In closing the orifice, which was done by a continuous silk suture, there was some difficulty in getting the sutures placed in tissue which would not tear out. On the fifth day the iodoform gauze drain which had been used was removed, and the temperature, which had been up to 101° F., became normal. In two weeks the wound had completely healed. During the fourth week the centre of the wound broke down, and it discharged freely for about ten days. On opening the abdomen for the purpose of closing this sinus, the intestine was found everywhere adherent, and, on attempting to break down the adhesions, the gut was torn completely across, so friable was the tissue. To repair this a resection of some two inches was done and an end to end anastomosis made. after which the abdominal wound was closed. From this time on there was no further trouble about the wound, but the patient did not regain his strength and occasionally had attacks of abdominal pain. The bowels were easily moved. Nearly a month after the second operation, an especially severe attack occurred, but his general condition was then such that operative interference could not be considered, and he rapidly grew worse and died, thirty-six hours after the beginning of the attack. The autopsy showed a volvulous of the sigmoid, with several inches of gangrenous intestine. This was far from the original seat of trouble and had no direct connection

The third case was that of a woman, forty-three years of age, a patient of Dr. Merzbach's, who made the diagnosis of probable intestinal perforation. Laparotomy was performed, and a punched opening, a quarter of an inch in diameter, entering the lumen of the gut, was found on the anterior surface of the transverse colon, about four inches from the hepatic flexure. The perforation was in the centre of an indurated area extending an inch around it, and all this area was excised. The opening in the colon was closed with silk Lembert sutures, and the patient was discharged from the hospital, cured, on the twelfth day.

The fourth patient, a boy of fifteen, had been operated upon for suppurative appendicitis six years before. Thirty-six hours before his admission to the hospital he was seized with violent abdominal pain, and the attack was characterized by vomiting, chills, fever, collapse symptoms, and some abdominal distention. Later the pain became localized below the umbilicus, just inside the scar of the previous operation, and a diagnosis of intestinal obstruction by a band or adhesions resulting from the appendectomy was made. When the abdomen was opened a coil of the ileum was found bound down to the lower lumbar vertebræ and perforated. In consequence of the firmness of the adhesion and the had appearance of that portion of the intestine, a resection was determined upon, about six inches of the bowel, including the area of perforation, being removed. Before closing the external wound, which was done without drainage, the abdominal cavity was thoroughly irrigated with normal saline solution and sponged out. The operation was attended with considerable shock, and for two or three days there was some febrile reaction with abdominal distention. From this time on recovery was uninterrupted, except for a slight point of infection at the lower angle of the wound, believed to be due to contact with fæces during the operation, and at the end of three weeks the patient was well. Dr. Delatour stated that twelve years ago he had reported seven consecutive cases of this accident, and in each the operation performed had proved little more than an ante mortem examination. He was therefore pleased to present now these four cases with practical recovery in all, since in Case II death had been due to an independent condition. This result, he believed, was largely due to an earlier diagnosis. Improved operative technique must, of course, be recognized as a decided factor, but this alone was not sufficient to account for the success. The one distinguishing feature in such cases was the sudden, sharp onset of pain, accompanied in many instances by symptoms of collapse. Following this was a period of apparent improvement, and it was just here that the danger lay; for if these patients were permitted to move about, the slight protective adhesions Nature had provided would give way. A general peritonitis would result, and an operation was then less likely to be successful.

A Corset for Visceral Ptoses.—Dr. A. ERNEST GALLANT gave a demonstration of his corset for visceral ptoses. The two special features of his method of treatment, he said, were replacement by posture and support without compression.

Dr. WILLIAM H. THOMSON said that chronic dysentery had long been one of the opprobria of medicine. A number of years ago he had pointed out that we should certainly not expect an ulcer of the leg to heal if it was subjected to the irritating and toxic conditions which intestinal ulcers were subjected to, and that the only rational treatment of the latter was to wash out the bowel after every evacuation. In these chronic cases he scarcely ever gave any medicine internally, and he had found the local treatment much more successful than any other. He was therefore much pleased to learn of the results accomplished by Dr. Gant, and said he was entirely willing to hand over to the surgeon all cases in which the seat of trouble could not be reached except by operative procedure. It might, indeed, be laid down as a settled fact that local treatment was the only rational method of treating any mucous surface. As regarded the bladder, for instance, this had long been recognized. When, some time ago, Dr. Weir had suggested to him the opening of the appendix as a new method for the treatment of mucous colitis, he (Dr. Thomson) had told him that he was delighted to know of this troublesome member being turned to any good use whatever. Autoinfection was the one great infection of the human race, and nothing could be more in accord with the lifelong desire he had had of controlling this infection in the intestinal canal than the successful achievement of Dr. Gant in this direction. In the matter of tympanites, we had, on account of the nerve supply involved, a far more difficult and extensive subject. The relation of the three cavities of the body, the cranial, the thoracic, and

the abdominal, to vitality was a most interesting question, and without doubt the abdominal cavity had a closer relation to this than both the others together. In the abdomen was situated the great solar plexus of the sympathetic system, and back of tympanites was the ominous significance of a great shock to life. In pneumonia, for instance, as Dr. Kemp had pointed out, it was important to watch the abdomen carefully. Acute dilatation of the stomach was here a very serious matter. There was imminent danger of fatal shock, for a toxæmia was producing an extremely severe vital depression. He had known patients who had passed the crisis, vet in whose cases the prognosis was uncertain. Gastrointestinal tympanites was a thing that he invariably kept in mind as a dangerous possibility, and he did not like to see a penumonia patient flat on his back. One of the many functions of the sympathetic was the making of substances which were real drugs, and the most powerful of these was adrenalin. The adrenal gland was more essential to life than the kidney, and it added to the bile a secretion which was an alkaline chemical agent, sodium taurate. Whenever tympanites had been produced, it meant that something had attacked the great centre of vitality. We had a toxæmia, and the question in pneumonia was not, to what extent was the lung involved, but how severely was the patient poisoned? So in typhoid fever. This disease presented three types. The first was one of pure toxemia, and the second one of hyperpyrexia. In the third the whole brunt was upon the intestinal tract, and this was the worst type. Repeatedly, when he had attended to the stomach, he had derived help from the hypodermic injection of eserine.

Dr. Einhorn thought that many of the cases referred to by Dr. Kemp, such, for instance, as those met with in migraine, were merely cases of atony, and not to be regarded as acute dilatation of the stomach. In diagnosticating this condition we must be guided more by the symptoms than by anything else. If there was distention of the abdomen with vomiting, the mobility of the stomach was interfered with, and the condition was really a grave one. The tympanites met with in pneumonia and typhoid fever was a symptom complex, and, as had been

said, was of septic origin.

Dr. JOSEPH MERZBACH said that acute dilatation of the stomach was by no means a very rare condition, and more frequently than not it escaped observation when present. In perforations of the gastrointestinal tract he agreed with Dr. Delatour that the success of an operation depended largely on the

matter of early diagnosis.

Dr. Joseph Kaufmann said that there was a tendency to attribute acute dilatation of the stomach too much to mechanical causes. This seemed to him to be a mistake, as he believed the condition to be really due to septic influences acting on the nervous centres controlling the stomach. One kind of acute dilatation had not been referred to by Dr. Kemp. namely, that produced by easily fermentable substances. In acute dilatation, such as the post-operative and other varieties, the effect on the heart was very marked. As to the treatment, he agreed with Dr. Kemp that lavage was the most efficient

means at our command, and he said he would employ it even where hæmorrhage was present.

Dr. John C. MacEvitt described a case of postoperative acute dilatation of the stomach which had been referred to in Dr. Kemp's paper. On the fourth day, after a supravaginal hysterectomy, symptoms simulating acute obstruction developed, and an exploratory laparotomy was performed. The stomach filled the abdominal cavity, extending into the pelvis. After insertion of the stomach tube three quarts of fæculent matter and much gas escaped, and the stomach gradually subsided to the normal.

Dr. Kemp said that acute atony and acute dilatation of the stomach were relative. A case might reasonably be described as one of acute dilatation, he thought, when the lower border of the stomach reached a certain point and the condition was accompanied with the symptoms described. Dr. Kaufmann had apparently misunderstood him as to the mechanical causation. In the vast majority of the cases acute dilatation was due to septic influences, and he had certainly intended autointoxication to be the keynote of his paper.

In reply to an inquiry as to what became of the fluid which was injected into the small intestine, Dr. GANT said that it was allowed to remain in the

bowel for twenty or thirty minutes.

New Inventions.

A FACE BANDAGE
By Frederic Griffith, M. D.,
New York.

The writer is convinced of two things regarding American surgery, namely, patients are kept in bed too long, and dressings are too bulky. Every day in hospitals throughout the United States one may see master surgeons at work whose knives never

falter, but who, in even routine, put patients back bed "two weeks" for this operation. "six weeks" for the other, and at the end the degree of pugnacity to get up manifested by the individual is taken into serious account. Before he goes to the cot, however, the operator has

swathed the section of body with turns and thicknesses of bandage, gauze, and cotton, much like the oldtime priests of Isis gave to a mummy notable.

Especially about the head, face, and neck our surgeons, aided by two now far famed men of memory, demonstrate their ingenuity. The fact remains that the lighter a dressing for these parts the better for the ease, comfort, and surgical welfare of the patient. Presence of suppuration, here

as elsewhere, indicates desirability for more frequent dressing of the wound involved rather than reliance placed upon bulk of material to hold pus secure from observing eyes of patient and his friends. Attention to the wound cleft before closure, seeking always dry surfaces for coaptation, gives better return in uncomplicated restorations than dependence in pressure and bulk of dressing to absorb subsequent oozing. Safety pins and raw cotton probably help the course of a trephine operation but little; to the same degree wobbling fragments in broken jaw which a chin splint and fourtailed bandage does not hold snug had better be wired at once rather than to rely upon memory and multiplication table to set a Barton Gibson dressing.

A light, retentive application which the writer saw employed by Italian surgeons after wounds of the face consists of a simple "four tail." Any portion of an individual's physiognomy between the malar bone and the angle of the jaw, and in front from the bridge of the nose to the mouth, can be adequately covered in. The patient's own ears are pegs of support for this dressing, as shown in the cut. The bandage may be made from a yard length of muslin roller two to six inches in width.

Book Antices.

IWe publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Nierendiagnostik und Nierenchirurgie. Von Dr. G. KAP-SAMMER. I. Teil. Mit 29 Abbildungen im Texte. Pp. xii-432. II. Teil. Mit 34 Abbildungen im Texte. Pp. xi-507. Wien und Leipzig: Wilhelm Braumüller, 1907. (Price, \$5.)

Kapsammer's work is one of the most important contributions to the subjects of renal diagnosis and renal surgery that have appeared since the publication of Casper and Richter's Functionelle Nierendiagnostik. The book is intended for specialists and special students, and all elementary details have been weeded out. Kapsammer has devoted a number of years to the study and experimental investigation of his theme, and as a result holds certain very positive views on the subject, especially with reference to the fallacies of some of the methods of functional diagnosis that have been proposed within the last ten years. He offers an array of facts and experiments in support of his views which are calculated to shed much light upon the cause of the uncertainty which has characterized many of the findings with such methods as cryoscopy, the methylene blue test, etc., and has lessened the popularity of these methods in clinical work.

The first volume deals with diagnosis; the second, with renal surgery proper. Opening with the subjective and objective signs of renal disease, the author passes on to the older methods of examining the renal secretion. These methods, including the determination of the specific gravity, of the percentage of urea, of the chlorides, and of albumin, are of great value in giving us clues as to the presence of anatomical lesions, but of no value in telling us the functional condition of the kidneys. Passing next to the new methods, including cryoscopy, the coefficients of refraction, of electroconductivity, etc., the methylene blue, phlorrhizin, indigocarmin, and other tests, each of these is described in detail as to technique, theory of action, results, etc. The most trustworthy of these methods, in the author's experience, is the phlorrhizin test, which is useful even when other tests fail.

The methods of separating the urine are considered next. The Nitze indirect catheterizing cystoscope has rendered the author the best and most trustworthy service. He has no use apparently for the direct catheterizing instruments so popular in this country, and in speaking of these omits to mention Tilden Brown, while Ayres is spoken of in passing (page 120) and Lewis's air cystoscope "without lenses" is spoken of as not worthy of further consideration (page 123). Kapsammer has not a single kind word for the "separators" or "segregators," including those of Luys, Cathelin, and others. These instruments are worthless for diagnostic purposes, and are not needed by any one who knows how to catheterize the ureters.

The next section, the most important in the book, deals with a study of the separate urines obtained by urethral catheters in both man and experimental animals. Kapsammer shows by these experimental data (1) that the weight of the kidney is rarely equal on both sides; (2) that there is always more or less difference in the amount of urine excreted by either kidney at the same time in normal animals, as well as in the amount of sugar excreted on either side normally after the phlorrhizin test; (3) that the presence of a ureteral catheter on one side leads to reflex polyuria on that side; (4) that the freezing point normally differs on the two sides, the difference being from -0.01 to -1.77° C. All these experiments were followed up by autopsies on the dogs tested, and normal kidneys were found in these animals. He, furthermore, found in normal persons quantitative differences in the secretion on either side, though these differences did not range so high as to interfere seriously with functional tests. The excretion of solids (absolute amount) was more constant on both sides than that of water, the latter fluctuating considerably at times. Contrary to the notions of Hermann, Landois, Ludwig, and other physiologists, there was no alternation of function whereby each kidney alternately took up the burden of excretion. The ratio of excretion between the two kidneys is a fairly constant one. Contrary to Albarran's view, the size of the kidnev has nothing to do with the amount of urine it secretes.

The most important anomaly of secretion resulting from the introduction of ureteral catheters is the reflex polyuria to which Kapsammer called attention as early as 1903. This polyuria occurs especially on the healthy side, so that the percentage of solids on that side is often lessened. Some urine also flows away alongside the catheters, making comparative tests less accurate. For these reasons a comparison of the specific gravity, urea, total solids, etc., on each side is of little value. A larger amount of albumin may be excreted by the healthier kidney, owing to the reflex polyuria on that side. or else owing to a toxic inflammation of that kidney, which is due to the disease in the other organ. Hence a quantitative comparison of the albumin-

urias on either side is of no value.

The reflex polyuria on the healthy side is also the "fly in the honey" in cryoscopy, for the freezing point on the healthy side may be as high as 0.00° C., while it may be lower (more normal) on the diseased side, where there is no polyuria and therefore a higher percentage of solids. With this Kapsammer practically sounds the death knell of cryoscopy, for if this method is of no value in separated urines, it is certainly useless in combined

urine (page 304). The methylene blue test as a comparative diagnostic method presents many factors of uncertainty, and has been practically superseded by Voelker and Joseph's indigocarmin test. Kapsammer was the first to show the value of this test with catheterism of the ureters, while Voelker and Joseph originally had intended it to supplant catheterism. The best and most reliable comparative test of renal function is the phlorrhizin test with ureteral catheters in place. Here, however, it is useless to estimate the comparative percentage of sugar in the urine (reflex polyuria again interfering); the time of appearance of the sugar should alone be taken as a criterion of functional efficiency.

In the second volume the various surgical diseases of the kidney are taken up in detail, and the application of the above described methods is illustrated in 182 case histories, all of which are given at length. Kapsammer's book constitutes a most valuable contribution to our present knowledge of the kidney, and is a monument to his ability as a clinician and his brilliancy as an investigator along one of the most difficult paths of surgical

progress.

BOOKS, PAMPHLETS, ETC., RECEIVED.

Anatomy, Descriptive and Surgical. By Henry Gray, F. R. S., Fellow of the Royal College of Surgeons; Lecturer on Anatomy at St. George's Hospital Medical School, London, etc. Seventeenth Edition, Thoroughly Revised and Reedited, with Additions, by John Chalmers DaCosta, M. D., Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College, Philadelphia, and Edward Anthony Spitzka, M. D., Professor of General Anatomy in the Jefferson Medical College, Philadelphia, Illustrated with 1,149 Engravings. Philadelphia and New York; Lea & Febicer, 1008. Pp. xxvi-33 to 1614. New York: Lea & Febiger, 1908. Pp. xxvi-33 to 1614.

Official News.

Public Health and Marine Hospital Service Health Reports:

The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon general, Public Health and Marine Hospital Service, during the week ending September 11, 1908: Smallpox-United States

Army Intelligence:

Official list of changes in the stations and duties of officers of the Medical Corps of the United States Army for the week ending September 12, 1908:

BARTLETT, C. J., Captain. Granted leave of absence to visit the United States, to take effect upon date of arrival in the United States of the transport Kilpatrick, and end-

ing September 15, 1908.

CRAIG, C. F., Captain. Detailed a member of a competitive examining board at Fort Leavenworth, Kan., vice Cap-

tain Bloombergh, hereby relieved.

DULIN, C. T., Medical Reserve Corps. Ordered to active duty in the service of the United States.

EBER, A. H., Medical Reserve Corps. Relieved from further duty in the Philippine Islands, and on expiration of his present leave of absence ordered to Fort De Soto, Fla.

Gosman, G. H. R., Captain. Relieved from duty at Fort Morgan, Ala., and ordered to Fort Barrancas, Fla., for station and duty.

HANSON, L. H., First Lieutenant. Ordered to Fort Sam Houston, Tex., for station and duty.

KEEFER, F. R., Major. Will proceed from the Presidio of Monterey to San Francisco, Cal., on or before September 10, 1908, reporting upon arrival to the adjutant general, Department of California, for assignment as acting chief surgeon of the Department during the absence of Colonel George H. Torney, chief surgeon.

YLE, F. T., Medical Reserve Corps. Ord duty in the service of the United States. Ordered to active

MILLER, A. L., Medical Reserve Corps. Granted twenty days' leave of absence.

PATTERSON, R. U., Captain. Granted leave of absence to visit the United States, to take effect upon date of arrival in the United States of the transport Kilpatrick, and ending October 15, 1908.

REASONER, M. A., First Lieutenant. Leave of absence ex-

tended four days

SHEPHERD, J. M., Medical Reserve Corps. Granted thirty days' leave of absence

The following medical officers have been ordered to Fort Myer, Va., September 16, 1908, for the purpose of undergoing the physical examination and testing their skill and endurance in horsemanship: Lieutenant Colonel Charles Richard, Major W. F. Carter, Major H. A. Shaw, Major F. A. Winter, and Major W. H. Wilson. Boards of officers of the Medical Corps, as hereinafter

constituted, are appointed to meet at the places designated for the purpose of conducting the examination of appli-cants for appointment as first lieutenant in the Medical

Cants for appointment as first fleutenant in the Medical Reserve Corps of the Army:

New York City: Lieutenant Colonel Charles Richard,
Major W. H. Wilson, and Captain E. P. Wolfe.

Washington, D. C.: Major W. D. McCaw, Captain J. B.

Huggins, and First Lieutenant J. R. Barber.

Columbus Descripto, Ohio: White H. G. Fisher, Captain

Columbus Barracks, Ohio: Major H. C. Fisher, Captain S. M. DeLoffre, and Captain L. J. Owen.

Jefferson Barracks, Mo.: Major A. E. Bradley and Cap-

Jefferson Barracks, Mo.: Major A. E. Bradley and Captain R. N. Winn.
Omaha, Neb.: Lieutenant Colonel Davis.
Fort Leavenworth, Kan.: Major E. L. Munson.
Fort McKinley, Me.: Captain C. W. Farr.
Key West Barracks, Fla.: Captain J. D. Heysinger.
New Orleans, La.: Major W. P. Chamberlain.
Fort Ontario, N. Y.: Captain G. P. Peed.
St. Paul, Minn.: Major F. P. Reynolds.
Fort Meade, S. Dak.: Major J. S. Kulp.
Fort Sill, Okla.: Major W. F. Lewis.
A. G. H. Presidio, San Francisco, Cal.: Major E. R.
Schreiner.

Schreiner.

Presidio, Monterey, Cal.: Major F. R. Keefer. Vancouver Barracks, Wash.: Major A. N. Stark. Ancon, Canal Zone, Panama: Major C. C. McCulloch, Jr.

Navy Intelligence:

Official list of changes in one stations and duties of officers of the Medical Corps of the United States Navy for the recek ending September 12, 1508

Boyn, J. C., Medical Director. Ordered to additional duty in command of the Naval Medical School Hospital.

Washington, D. C.

Dessez, P. T., Passed Assistant Surgeon. Detachéd from
the Chicago; unexpired portion of leave revoked; and
ordered to duty at the Naval Hospital, Las Animas,

HATHAWAY, G. S., Assistant Surgeon. Ordered to duty in connection with fitting out the Wyoming and to duty on board that vessel when commissioned.

on board that vessel when commissioned a Hennemerker, L. G., Medical Director. Commissioned a medical director, from September 2, 1908.

MINK, O. J., Passed Assistant Surgeon. Detached from the naval recruiting station, Chicago, Ill., and ordered to the Naval Medical School, Washington, D. C.

Percy, H. T., Medical Inspector. Commissioned a medical inspector, from September 2, 1908.

ROMAN, S. S., Passed Assistant Surgeon. Unexpired portion of leave revoked: ordered to the naval recruiting

tion of leave revoked; ordered to the naval recruiting Station, Chicago, III.
WHEELER, W. M., Surgeon. Ordered to the navy yard,
New York, September 12th.

Wise, J. C., Medical Director. Detached from command of the Naval Medical School Hospital, Washington, D. C., and ordered to duty as a member of the naval examining and naval medical examining boards, Washington, D. C. ington, D. C.

Births, Marriages, and Deaths.

Rorn

STRINE.—In Greensburg, Pennsylvania, on Sunday, August 30th, to Passed Assistant Surgeon Howard F. Strine, United States Navy, and Mrs. Strine, a son. WILLCOX.—In Camp Columbia, Cuba, on Wednesday, August 19th, to Major Charles Willcox, Medical Corps of

the United States Navy, and Mrs. Willcox, a daughter.

Married.

Coles—Lippincott.—In Bryn Mawr, Pennsylvania, on Monday, September 14th, Dr. Stricker Coles and Miss Bertha H. Lippincott, of Philadelphia.

SOME CONSIDERATIONS OF EXOPHTHALMIC GOITRE FROM THE MEDICAL STANDPOINT.*

> BY ALFRED STENGEL, M. D., Philadelphia.

It is generally conceded that the essential pathology of exophthalmic goitre, or Graves's disease, consists in a hypertrophy or hyperplasia of the secretory cells of the thyreoid gland. If it were possible to have portions of the gland removed in every case it would be easier to reach reliable conclusions as to the pathology in all varieties of the disease than has thus far been possible. The present day views regarding the pathological anatomy of the disease are based upon studies of the glands obtained from cases of a more or less advanced character, with established and often long standing changes in the structure of the thyreoid gland. There is, however, a group of cases, by no means small in point of numbers, in which enlargement of the thyreoid gland or goitre may occur with symptoms of hyperthyreoidism more or less pronounced, and in which a spontaneous cure or recovery under treatment may occur in a relatively short time. When the symptoms are pronounced, one is not in much doubt regarding the justification of calling the condition Graves's disease, irrespective of the circumstances antedating the thyreoid enlargement and the symptoms of hyperthyreoidism. When, on the contrary, only moderate enlargement of the gland is observed and the evidences of hyperthyreoidism are ill developed, great difficulty is encountered in deciding upon a proper diagnosis. Temporary enlargements of the thyreoid gland are known to result from various trivial causes, such as menstruation, pregnancy, and emotional conditions. In these cases no symptoms of functional derangement or inactivity of the gland usually occur, and we cannot escape the conviction that the enlargement of the gland is simply congestive or due to some other unimportant and ephemeral swelling of the organ. There are other conditions in which a more persistent enlargement of the gland, still, however, as a rule without marked functional effects, is met with. Among these conditions anæmia, especially chlorosis; circulatory disorders; and nervous conditions or diseases are notable.

1. Anæmia, with thyreoid enlargement and symptoms of hyperthyreoidism. If one examines a series of cases of advanced chlorosis, enlargement of the

*Read at a meeting of the New York Academy of Medicine, April 16, 1998.

thyreoid gland will be encountered in a large proportion of them. There may be associated with this some tremor, palpitation, and rapidity of the heart's action, moisture of the skin, and fullness of the eyes. These symptoms individually or collectively may indicate nothing other than the results of the anæmia. In some cases, however, the symptoms enumerated are so marked that one cannot avoid the conclusion that they are the result of hyperthyreoidism. The difference between the former and latter groups is conceivably one of degree only. Chlorosis may in the former group occasion an enlargement of the thyreoid gland of an unimportant character and without such an overaction or perversion of function as to cause symptoms of hyperthyreoidism. In the second group, the process set up in the gland is of a more pronounced character, and hyperthyreoidism results. Whether we should call such cases Graves's disease or adopt a roundabout expression such as "enlargement of the thyreoid gland with hyperthy-reoidism" cannot be settled offhand. Something will be said upon this head after the other conditions, in which a similar state of affairs arises, have been mentioned.

2. Circulatory disorders. In mitral disease and in other forms of cardiac hyposystole with venous congestion, some enlargement of the thyreoid gland is not infrequent. As in the case of chlorosis, two groups may be distinguished; a larger, in which symptoms of hyperthyreoidism are not demonstrable, though cardiac irregularity and rapidity, tremors, sweating, and even fullness of the eyes may be present as a result of the circulating derangement; and a second small group in which pronounced symptoms

suggestive of hyperthyreoidism appear.

3. Nervous conditions and diseases. Emotional disturbances are known to cause some enlargement of the thyreoid gland in certain persons, and it is well known that the symptoms of sudden fear or fright as described by Darwin in many respects bear a resemblance to the symptoms of Graves's disease. Even exophthalmos is suggested in some of the illustrative pictures in the Expression of the Emotions in Man and Animals. Medical literature contains a number of instances of acute Graves's disease resulting from fright or emotional excitement and terminating in rapid death or, on the other hand, in a chronic form of the disease or in spontaneous recovery. These several terminations may be regarded as significant of different grades of severity of the disorder of the thyreoid gland and the whole organism or of different degrees of resistance. The mildest cases furnish little ground for a diagnosis of Graves' disease and their spontaneous cure or their rapid recovery under ordinary treatment is convincing of the nonexistence of any extensive organic lesion. Those who are disposed to deny the applicability of the theory of hyperthyreoidism to Graves's disease will find in these cases and in the review of the whole question of the effect of violent emotions in man not a little to support their beliefs. It would carry us too far into speculation to attempt to answer this argument; but it may be stated categorically that there are doubtless instances of enlargement of the thyreoid and symptoms suggestive of hyperthyreoidism following fright, etc., in which the whole syndrome is the result of nervous conditions per se, while there are other cases in which the suggestive symptoms are truly the result of hyperthyreoidism, occasioned by disorder of the thyreoid gland, due in turn to the nervous disturbances. In clinical experience difficulty may arise in reaching a conclusion as to the significance of thyreoid enlargement and the associated symptoms in organic as well as functional nervous states. I recall a recent case in my own experience in which there was associated with a condition of dementia præcox distinct thyreoid enlargement and some suggestive symptoms of Graves's disease. I also remember a case of ascending (Landry's) palsy, in which symptoms of Graves's disease (goître, protrusion of the eyes, tremors, tachycardia) preceded the final development of bulbar symptoms and death. In cases like these two it is difficult to escape the conviction that the thyreoidal phenomena were merely secondary, and not to be interpreted even as acute Graves's

What importance, it may be asked, attaches to the discussion of such cases of doubtful or larval exophthalmic goître, occurring in the conditions described? In answer to this question I wish to state that (1) it is well to recognize that larval cases, in which there is temporary and mild hyperthyreoidism, not infrequently present themselves; (2) in estimating the seriousness of the disease as a whole and its amenability to various forms of treatment. the occurrence of such cases and their usual mild character should be taken into account; (3) in attempting a classification that may be of use in directing proper treatment, these cases should be distinguished from what may be termed true Graves's disease, a condition in which fixed (not merely transient) lesions of the gland are the occasion of the hyperthyreoidism.

It is a notorious fact that much difference of opinion exists in the profession regarding the curability of Graves's disease. It seems to me that this is most probably due to the differences in the cases embraced under that term. Those who have included only cases with more or less durable disease of the thyreoid and with marked symptoms of hyperthyreoidism have naturally expressed more guarded views of the prognosis. Those, on the other hand, who have included all cases in the sense of what has previously been stated in the discussion, have reached a very different conclusion. Published statistics are of but little value, because the character of the cases included in the various series has d while started. As a matter of record, Dusch 115 ed the mertality at 12.5 per cent.; von Graefe at ten per cent.; Charcot at twenty-five per cent.; Ord and Mackenzie at about twenty-three per cent.; and in Buchan's statistics there are recorded only 105 deaths among 900 persons. It is, of course, admitted that many of the cases not recorded as fatal were only partially improved, and it might properly be asked if the eventual outcome was not really a false one. The same difficulty arises here as in the case of many other chronic diseases. A truer estimation of the seriousness of the disease is obtained by determining the frequency of recovery. Ord and Mackenzie state that "in about fifty per cent., more or less, complete recovery will eventually take place." Dana states a similar belief. Surely no such flattering figures could be quoted if only the type cases of Graves's disease, such as we see in hospital wards and demonstrate in our clinics, were included.

If, then, for purposes of proper classification, looking to the adoption of proper remedial measures, it is desirable to separate milder cases of hyperthyreoidism from Graves's disease proper, what are the data upon which reliance can be placed? In answer to this question I would propose (1) that the character of the thyreoid enlargement and the other clinical manifestations be considered, and (2) that the associated diseases, such as anæmia, circulatory disorders, and nervous conditions, and antecedent history be taken into account. (1) The gland in genuine Graves's disease is usually enlarged in such a manner that the fixed organic character of the condition is recognizable. It must not be forgotten, however, that in instances of purely acute thyreoiditis, hardness and more or less nodularity may suggest a chronic condition, while, on the other hand, cases of genuine chronic Graves's disease may present little thyreoid enlargement and no induration whatever. The history of the glandular enlargement is, of course, to be considered. If the symptoms associated with thyreoid enlargement of a trivial sort are equally trivial, further support will be lent to the assumption that the case is one of little gravity. (2) Enough has been said regarding the occurrence of doubtful, larvæ, or true Graves's disease in association with anæmia, circulatory troubles, and nervous conditions. If the association is remembered, mistaken forebodings will in many cases be avoided.

As to previous history, I wish to refer to the probability that many instances of Graves's disease possibly have their origin in the conditions alluded to, which had been allowed to remain uncorrected, and also to the probable origin of Graves's disease in various acute infections. I remember particularly a case of acute thyreoiditis, with decided evidences of hyperthyreoidism, which followed a streptococcic infection of the pharynx and larynx. The patient, a physician, recovered fully after rather prolonged rest, with applications of ice to the enlarged gland and other appropriate treatment. Other cases with a similar if less striking sequence might be alluded to. The importance of referring to such cases consists in the fact that the thyreoid condition and the resulting symptoms might readily be overlooked in the course of severe infections or in the convalescence from them. As a matter of fact, the thyreoid condition, in the

patient referred to, was overlooked in the begin-

It seems to me that the alert clinician may not rarely recognize thyreoid diseases in their incipiency, and by vigorous treatment obviate the more serious lesions that may subsequently prove the basis of a

genuine chronic Graves's disease.

Before closing, I wish to mention some of the symptoms less commonly discussed. First, the condition of the blood, and the question of the occurrence of lymphocytosis. My personal experience indicates that this is not a sign upon which reliance could be placed. Second, in some cases enlargement of the lymphatic glands in the neck is met with, but my experience would hardly justify me in placing any reliance upon this as a diagnostic point. This sign is too irregular in its appearance to be of any material aid in diagnosis. Third, enlargement of the thymus gland. This condition, though of regular occurrence, is so difficult to diagnose that it fails to give any practical information. Fourth, the general condition of muscular adynamia and gastrointestinal symptoms. These are more important than is generally held. In a discussion of Graves's disease, writers often speak only of the cardinal symptoms; but in the recognition of doubtful cases more importance should often be attached to muscular adanamia and to gastrointestinal conditions than to some of the so called cardinal symptoms. Palpitation of the heart, tremor, etc., occur so often in other conditions that their diagnostic value is not very great.

With regard to Graves's disease being secondary to other thyreoid disease, clinicians recognize this to be true. Such cases are of long duration before symptoms of hyperthyreoidism set in, and their

clinical manifestations are usually mild.

To summarize, the practitioner has to deal with

three important types of Graves's disease:

(1) Cases of moderate enlargement of the thyreoid gland, with mild symptoms of hyperthyreoidism, occurring in either constitutional, or circulatory, or nervous conditions, and which usually get well.

(2) Typical cases of hyperthyreoidism associated with fixed organic changes in the thyreoid gland. These are the cases of classical Graves's disease. These may or may not get well under medical or surgical treatment.

(3) Cases of long standing goitre or other thyreoidal disease, in which symptoms of Graves's disease supervene. Such cases belong to the domain

of surgery.

1811 SPRUCE STREET.

THE EARLY RELATIONSHIP OF THE OOSPERM TO THE ENDOMETRIUM.

By James Oliver, M. D., F. R. S. (Edin.), F. L. S., London, England,

Physician to the Hospital for Women

There is a general belief that when the fertilized ovum in the human female arrives in the uterus its detention therein is due either to the decidua growing up around and so enveloping it that it becomes lodged in an accessory ovigerous chamber constituted largely of the so called decidua reflexa or to the oosperm penetrating the endometrium and embedding itself to a greater or less extent in the uterine wall, the decidua thereafter closing rapidly over it in the form of a so called decidua capsularis. In either case, it is alleged, an adventitious chamber is formed, which serves to retain the oosperm in, but, nevertheless, excludes this body from the cavity of the uterus, and the mechanism whereby this is effected is in the two cases very dissimilar. In the former the entire chamber results from a localized overgrowth of the inner lining of the uterus and without the expenditure practically of any energy on the part of the oosperm, whereas in the latter the endometrium is attacked by the oosperm, which bores its way into the substance of the uterus, not through the agency of any vital pressure, but through the limited action of some solvent secreted by the oosperm itself; the breach thus created being rapidly repaired by a so called decidua capsularis.

The uterus is specifically endowed for the process of gestation, and under ordinary circumstances it responds so readily to the stimulus of an oosperm that without let or hindrance it offers a sufficiency of those materials which are requisite and necessary for embryonic development and growth; consequently we must banish from our minds the idea that the oosperm is at any time in any sense of the

word a parasite.

Too unhesitatingly, in my opinion, and on very slender testimony indeed, it has been admitted and proclaimed that the oosperm is detained in the cavity of the uterus in some sort of decidual envelope.

Let me here recall some facts concerning the subject of placentation in the lower animals, as we may thereby glean some very valuable information. In cetaceæ the germ mass from first to last is everywhere placental, so that during the whole period of gestation in this mammal the processes of metabolism in the embryo are carried on by diosmosis through the agency of the entire chorion, the mucous lining of the uterus in its whole extent being at the same time both a secreting and an absorbing structure. In this case the villous bodies of the whole chorion are to all intents and purposes similarly endowed, there is no functional distinction. In the horned ruminants we find a remarkable modification of this universal placenta; some villi atrophy but here and there over the entire surface of the chorion groups of villi hypertrophy and growing more and more form eventually many separate placentulæ. These patchy overgrowths in the chorion correspond with and are correlated nutritively to cotyledonary processes or caruncles which may be observed studding the interior of the uterine horns in these animals. In the cow these cotyledonous placentulæ are sometimes exceedingly numerous; in individual cases as many as eighty have been detected. Again, in the cat and carnivorous animals generally the placenta is more or less annular in shape, the villi participating in its formation being grouped together like a belt, whilst the villi over the rest of the chorion have practically vanished.

In all the lower mammals, not even excepting the monkey, the germ mass is detained in the uterus neither by a decidua reflexa nor yet by a decidua capsularis, but by osmotaxis and chemiotaxis, and under ordinary circumstances these same agencies in the human female cause not only a halt, but

arrest the progress of the oosperm immediately this body reaches the cavity of the uterus. The condition of affairs, which obtains in the lower mammals, does not encourage us to accept the tenet that the oosperm is ever lodged in an accessory chamber in the cavity of the uterus, and clinically we are justified in rejecting the dogma altogether. If we assume that encapsulation takes place through the oosperm secreting some substance which attacks and eats away a limited portion of the uterine wall it is, nevertheless, impossible for us to believe that in this procedure Nature would never err, and that we should never find some evidence of this solvent material exceeding its physiological function and causing a too extensive destruction of the uterine tissues. Errors of this kind are often observed. Take the dissolutionary changes which should restore the uterus to its normal state after parturition. These dissolutionary changes may transcend the usual amount and may leave the uterus in a state of superinvolution, the utility of the organ being for-ever thereafter annulled. Similarly in the oosperm itself, when about the fifth or sixth week of pregnancy, the utility of the villous bodies constituting nearly four fifths of the chorion is abolished, the atrophic process may invade the placental as well as the nonplacental area, causing a hyperatrophy of the villous bodies of the chorion, and no placenta

or a very inefficient one may thereby result. In the human female, after the fifth or sixth week of gestation, metabolism in the embryo is effected through the medium of a limited portion of the endometrial lining, the decidua placentalis; but prior to this, both before and after the whole villous surface of the chorion becomes vascular, the well being of the embryo is maintained by diosmosis through the entire periphery of the germ mass, and in this phenomenon the lining membrane of the whole cavity of the uterus participates. During the first five or six weeks of gestation, therefore, the human embryo is nourished in the same way as a cetacean fœtus during the whole period of pregnancy, and it is difficult to believe that in the former case Nature would furnish either a decidua capsularis or a decidua reflexa, and render nugatory thereby practically one half of the villous surface of the chorion. Moreover, in consequence of some breach in the continunity of the rapidly enlarging vessels in the decidua placentalis, hæmorrhage from the external genitals is often observed towards the sixth week of pregnancy, and in spite of a prolonged continuance of free hæmorrhage from this quarter the development and growth of the embryo may proceed uninterruptedly and the fœtus may be and very frequently is carried to maturity. however, a decidua capsularis or a decidua reflexa existed it is very evident that no blood emanating from the actively enlarging maternal vessels could escape externally without bursting the accessory ovigerous chamber, and this would either sweep the embryo away or speedily cause its death. Again, complete placenta prævia becomes an unthinkable condition if we believe that the germ mass in the uterus is ever harbored in a secondary chamber. Once more, it sometimes happens that the placenta is composed of two lobes, separated by a greater or less amount of nonplacental chorion, and one of ...

these lobes may be implanted on the anterior, whilst the other is implanted on the posterior wall of the uterus, the nonplacental part uniting them being located at the fundus. Under such circumstances it is inconceivable that a decidua reflexa, and still more a decidua capsularis, could ever have been evolved.

18 GORDON SQUARE.

INJECTION OF ALCOHOL FOR RELIEF OF TRI-GEMINAL NEURALGIA.*

BY JOHN A. BODINE, M. D.,
New York,
Professor of Surgery, New York Polyclinic,
AND FREDERICK C. KELLER, M. D.,
New York,
Lecturer on Surgery, New York Polyclinic.

The contents of this paper are based upon a clinical experience of fifteen cases of trigeminal neuralgia, in which deep injections of alcohol were given for the relief of pain. From partial to complete relief has been afforded in every case. The measure of the quantity of relief has, of course, been decided by the patient's statement, as, in fact, the diagnosis of the disease also. We have accepted as diagnostic of trifacial neuralgia the statement of any patient of more or less continuous pain within the area of distribution of any or all branches of the fifth cranial nerve. The time covered by this experience is only six months. The method used is that recommended by Lévy and Baudouin, the technique of which is simplicity itself. It consists of injecting two cubic centimetres of alcohol more or less diluted into or near one or all of the three divisions of this nerve at their basal foraminal exits in the skull.

Summary of our Experience.

CASE I.—First injection December 11, 1907. Absolute relief after one injection to the present time, with a short intervening period of return of neuralgia.

Case II.—First injection January 4, 1908. Partial relief after two injections to March 4th, when

patient was lost sight of.

CASE III.—First injection January 25, 1908. Absolute relief after six injections to present time (June 27th).

Case IV.—First injection January 25, 1908. Complete relief for one week after first injection.

Failed to return after second injection.

Case V.—First injection February 15, 1908. Very slight relief after six injections of second and third divisions. Marked relief after injection for ophthalmic division.

Case VI.—First injection February 28, 1908. Complete relief after one injection to present time.

Case VII.—First injection March 7, 1908. No

relief after one injection.

CASE VIII.—First injection March 21, 1908. Great relief after seven injections to June 13th, when last seen.

CASE IX.—First injection April 1, 1908. Com-

plete relief after one injection.

"Read but in the Section is Neuroleany of the New York Acidemy Western Meeting ages CASE X.—First injection April 6, 1908. Absolute relief after four injections to June 21st, when last seen

Case XI.—First injection April 7, 1908. Complete relief after three injections to April 30th, when last heard from.

CASE XII.—First injection April 8, 1908. Complete relief after one injection to April 17th, when last seen.

CASE XIII.—First injection June 17, 1908. Almost complete relief after one injection to June 24th, when last seen.

Case XIV.—First injection June 20, 1908. Complete relief after one injection to June 24th, when last seen.

CASE XV.—First injection June 27, 1908. Partial relief after one injection to July 1st, when last heard from.

Such limited experience as we have had, the paucity in number of cases and shortness of time since first injection, would imply presumption in this paper if it aspired to the dignity of a conclusion as to the value of the treatment under consideration. However, no such presumptive ambition is entertained by the writers, and the full scope and measure of this communication is to serve as a peg upon which to hang your discussion.

In accordance with this apologetic foreword, we shall eliminate the conventional historical and statistical introduction to the subject, though it is but right that credit and acknowledgment for instruction and valuable work in this line be given to Fothergill, Bartholow, Eulenberg, Jacoby, Wright, Bennett, and Murphy for their efforts to secure an injection of pain deadening or nerve destroying substances, and to bring relief to the agonized sufferer with tic doulowreux, the pain of which no other medical or surgical disease parallels. We owe great and specific credit to Schlösser, Ostwalt, Lévy, and Baudouin for the method under consideration.

This method consists, in brief, of the injection of alcohol, more or less diluted, into or near the nerves at the basal foraminal exits of the skull. We probably do not often succeed in actually inserting the tip of the needle into the nerve sheath, but by following the simple directions laid down by Lévy and Baudouin, the point of the needle rests within a very small fractional part of an inch of the nerve trunk at its exit. The alcoholic solution probably comes in contact with the nerve trunk by diffusion. There is at times a characteristic sudden, shooting pain within the area of distribution of the nerve trunk injected, and we have taken this to mean that the nerve itself has been touched by the point of the needle. Again, this characteristic manifestation is absent, and yet the injection has invariably, in every and all of our cases, given more or less relief for a longer or shorter period of time.

As the point selected to reach the nerve and the depth of penetration of the needle are calculated upon fixed bony points of the skull, the same inaccuracies are encountered as are so well known in craniocerebral topography. Not only differences actually exist in different heads, but the two sides of the same head may and do differ. It is not only possible, but probable, that further study along this line may develop greater accuracy in striking the nerve

trunk, and as a suggestion, a line of study based upon percentage measurements of different skulls made in the metric system, may determine this accuracy, just as Chipault's method of craniocerebral localization has done in brain surgery. We are satisfied of one thing, that the injection of these nerves is so simple and so safe as not to require the services of a specialist. In marking out our own line of work before our actual experience began, we studied the methods of Schlosser, as outlined by Kiliani, of Ostwalt, and of Lévy and Baudouin. We selected the method of Lévy and Baudouin because of its simplicity. The methods of all these gentlemen differ only in the point of entrance and direction of the needle in its search for the nerve trunk. We shall describe only the method of Lévy and Baudouin.

To reach the superior maxillary branch, a point is determined on the lower or inferior margin of the zygomatic process precisely vertically under the posterior border of the orbital process of the malar bone. One half centimetre posterior to this line, that is, towards the ear and at the lower edge of the zygomatic arch, the needle is inserted. Its general direction is upward, and it is pushed into the pterygomaxillary fossa to the depth of five centimetres. The needle is graduated in centimetre marks, so this depth of penetration is easily determined. At this depth two cubic centimetres of the alcoholic solution are injected. As a rule, if we did not obtain the characteristic symptoms of touching the nerve trunk, no further effort was made to find it at that sitting. We knew by study upon the cadaver that the point of the needle was in exceedingly close proximity to the nerve, so the injection was made. Once or twice we struck the coronoid process with the point of the needle at about half the required depth, but it was only necessary to carry the needle slightly forward to pass this obstruction. For injection of the inferior maxillary branch, the descending root of the zygomatic arch is identified and located by the finger in front of the ear. At a point two and a half centimetres anterior, precisely at the lower edge of the zygoma, the needle is inserted and carried to a depth of four centimetres, where the injection is made

For the ophthalmic or first division, the rule as laid down by Patrick and Hecht, of Chicago, is as follows: "The needle is passed along the outer wall of the orbit, at the level of the inferior extremity of the external angular process of the frontal bone. It passes beneath the lachrymal gland, safely away from the eye ball, hugging the orbital periosteum, and at a depth of three and one half to four centimetres, injection is begun. We have had one experience with injecting this branch. It offered to our minds theoretical possibilities of damage that have, so far, largely deterred us from its attempt. Fortunately for this method, the second and third divisions of the trigeminal nerve are the ones most frequently affected, though it may be proved later that injection of the first or ophthalmic division is without danger to the structural integrity

The solution used in all of our cases was two cubic centimetres (for each branch injected) of the following:

Cocaine hydrochloride, grain; Chloroform, 10 minims; 3 drachms: Distilled water,q. s. to make 1/2 ounce.

Nearly all injections have been made at the basal foramina, but few at the peripheral exits of the

One contemplating this deep injection would naturally be assailed with doubt in his mind as to the certainty of reaching the right spot, and while we believe this method to be within the skill of the average medical or surgical man, practice upon the cadaver is strongly to be recommended. All of the injections in our series of cases have been made by the junior author of this paper, and he has, by practice in the deadhouse; easily acquired the dexterity to touch the foraminal exits of the nerves in eight out of ten cadavers. This accomplishment is within the means of any one who can give a few nights' time for practice in the deadhouse. If any dangers attend the deep injection of the second and third branches, they are not known to practice, nor can they be conceived theoretically. The danger of hæmorrhage is reduced to a minimum by the blunt cutting point of the needle used. Beyond a more or less extensive subcutaneous ecchymosis, we have, so far, seen no evidence of excessive hæmorrhage. The danger of sepsis carried to the depth of needle penetration is an actual one. It was for this reason that we discarded the Ostwalt method of reaching the nerve, because the needle enters through the mucous membrane of the mouth.

Preliminary anæsthesia of the skin at the point of needle entrance with weak cocaine solution or plain water, then division of the skin by incision with the point of a bistoury, allows easy entrance of the needle point without danger of carrying the infection always resident in the depths of the skin. Our injections were made usually at the clinic. Sometimes when we did not get the characteristic expression of having touched the nerve, we have injected twice at the same visit. There was only once any shock or unpleasant symptom attending the procedure. As to the pain of the injection complained of by the patient, it varies considerably. Some complained bitterly, and some said that "it didn't hurt at all."

A skeleton outline of our case histories is as fol-

CASE I.—P. P. Seventy-three years of age. Laborer. Neuralgia began seventeen years ago. All teeth on his right side were sacrificed in effort at relief. Twelve years ago he was operated upon. Scars of the face indicate that the operation was one of division of nerve at infraorbital foramen and at angle of the lower jaw. Relief for two years. Recurrence of pain, and a second operation in 1898 by Dr. Abbe. The scar would indicate a trauszygomatic approach to the nerve trunks. Relief followed for ten years, and then recurrence of the neuralgia. December 11, years, and then recurrence of the neuralgia. December 11, 1007, injection into the second and third division by the method and solution detailed in this paper. Patient reported at clinic one week later free from pain, some swelling of the face persisting. Reported again, still free from pain, one month later. Was at that time able to eat and smoke without discomfort, a blessing denied him for the year previous. February 24th, some twinges of pain companied of in the texth and guns of the lower inv. February 24th, some twinges of pain companied of in the texth and guns of the lower inv. February 24th, some twinges of pain companied of in the texth and guns of the lower inv. February 24th. plained of in the teeth and gums of the lower jaw. February 26th, patient refused another injection because he did not think the pains sufficient to demand it. He is presented here to-night. March 14th, patient says he feels "fine." Looks cheerful. June 3d, relief continues.

CASE II.—L. S. Seventy-eight years of age. Carpenter.

Under medical care of Dr. Pritchard. Neuralgia of left side, confined to second and third divisions, one year's duration. Injection of both nerves January 4th. Considerable complaint of pain at time of introducing the solution. Two weeks later patient reported no improvement. A second injection was made, and on February 15th he reported considerably relieved, though not wholly free from pain. Can eat and talk now without exciting a paroxysm. Notable improvement in his looks and actions attested by his family. He seemed and expressed himself free from pain in face and jaw, but complained of a persistent pain in his tongue. On March 4th, the patient reports "in about the same condition," greatly relieved, but still not entirely comfortable. Refused another injection. June 22d, patient could not be

Case III.—A. W. Fifty-five years of age. Cook. Right sided neuralgia involving second and third branches. Began fourteen years ago. Case was quite typical. She could not chew at all, and her diet consisted for years of líquids. Said that almost every night she was awakened by an attack, and had to walk the floor, or sit up. During attack

there was lachrymation and drooling.

Had had two operations, the first six years ago, infra-orbital avulsion as indicated by the scar. Relief for six months. A second operation last April, infraorbital, but not followed by relief. During all these years she had been treated at different clinics by medication. For the last few weeks she had been under the care of Dr. Pritchard.

The patient had six attacks, quite severe, but of short aration, on her first visit to the hospital. Injection Janduration, on her first visit to the hospital. uary 25th, second and third division. Following this injection there was a complete and almost magical cessation of pain. She could sleep all night and chew solid food or pam. She could sleep all night and chew solid food without discomfort. February 19th, she reported her condition as perfectly comfortable, though an occasional little twitch of pain in the face. These twitches continued until March 7th, when she had rather a severe paroxysm. She was again injected. March 11th, supraorbital paroxysms, several severe attacks while awaiting injection. In addition to the usual deep injection, an injection was made into the supraorbital foramen. March 21st, entire freedom from pain since last injection. Patient very grateful and happy. March 29th, had no pain, but said she would feel safer if injections were repeated. April 5th, relief continued. Patient had gained ten pounds during past month. May 25th, slight attack of pain this morning. June 2d, sixth injection, patient having some pain when chewing. Last seen June 27th, when she left town. Complete relief. Still gaining weight. Eat and slept well. Cheerful and grateful. Case IV.—L. D. Twenty-nine years of age. Laborer. Referred by Dr. Steinach. First attack dated five years ago, and occurred now and then at intervals of several days or a week, on the right side. Within the last year the atto the usual deep injection, an injection was made into the

or a week, on the right side. Within the last year the attacks had increased in frequency, and are at present almost continuous. Had been through the usual gamut of medicinal treatment, electricity, x ray, etc. Injection, January 25th, second and third divisions. Reported one week later almost free from pain. Could shave, chew, and do other things without discomfort that before excited the attacks. February 26th, patient had recurrence of his old trouble in all of its atrociousness. Injection of the third division caused him great pain; patient refused to allow injection of the second division at this sitting, and did not return for

further treatment.

further treatment.

CASE V.—L. S. Twenty-nine years of age. Laborer.

Patient of Dr. Steinach's. Right sided neuralgia, confined to the temporal region. We could not elicit pain in any other distribution of the nerve. Attack excited by chewing. Pain constant, day and night, for over a year. Trouble of six years' standing. This pain seemed to be limited to an area of about one and one half inches from above the right eye to the hair line. Lachrymation on this side.

Injection February 15th, second and third divisions of the nerve. Patient experienced the characteristic pain that here-

nerve. Patient experienced the characteristic pain that heretofore had indicated to us striking the nerve trunk with the needle point. February 19th, patient reported that, while pain was temporarily relieved by the injection, it had returned. Another injection into the second and third divisions made. This, according to patient's statement, reduced the severity of the attacks, but had not abolished them. A third injection was given March 7th. March 10th, workled the Inselficient to deep injection into a principle into no relief. In addition to deep injection, an injection into or near the supraorbital nerve at the foramen or notch. This gave relief for two days. March 14th, pain as severe a continuous for second and for third division and

into supraorbital foramen. Relief for a few days. March 18th, injection for second and for third divisions. March 25th, fourth supraorbital injection followed by relief for only half an hour. March 28th, severe pain in temporal region and on top of head. First injection for the ophthalmic division through the orbit. The introduction of the needle caused severe pain, and the injection even more pain, in the eye and on the forehead above the eye. This pain subsided after a few minutes. Immediately after the injection analgesia in the area of the supraorbital distribution on right side. Upper eyelid slightly swollen immediately after injection, and patient was unable to raise it. Sight perfect. Fifteen minutes after injection patient left for home, completely relieved and cheerful. March 29th, patient reported that about two hours after the injection yesterday the temporal pain returned and was present all afternoon. He slept well during the night, and was free from pain when he awoke this morning. Marked cedema of upper lid and forehead. Patient failed to return, and it was learned on inquiry, April 24th, that he had removed from the address given.

CASE VI.—Mrs. M. Sixty-eight years of age.

wife. Typical neuralgia of the intense type for fourteen years. Had tried many methods of treatment, excepting operation. Her father was a sufferer for many years from trifacial neuralgia. Injection of second and third divisions February 28th at patient's home. No particular complaint of pain from the introduction of the needle. However, a very rapid and angry looking cedema followed within a few minutes after withdrawal of the instrument, and the ecchymosis during the next few days reached almost to the clavicle of that side. It was quite probable that we wounded a vein of some size. This patient was a dainty old lady of the lace and lavender type, and it was interesting to ques-tion her about the pain and discomfort of this method of treatment. She felt the characteristic twinges when the needle reached the nerve, and yet, on the whole, she considered the pain of the injection insignificant. Complete relief

has been attained so far.

CASE VII.—Widow. Sixty years of age. Duration of attacks only about six months, but had developed considerable severity and frequency, excited by opening mouth, chewing, or washing face on this side. Previous history nega-Previous history negative. Injection of second and third divisions. Characteristic twinges of pain indicated the accuracy of the needle point. Patient did not return after injection, and in June search was made for her. She had been married in mean-time, and was found at a new address. June 27th she re-ported at the clinic. Said she had not been relieved. Refused injection.

Case VIII.—F. P. Male. Forty-eight years of age. Janitor. Patient of Dr. Pritchard. Neuralgia four years. Constant pain in left half of tongue, mucous membrane of left cheek and gums. Many paroxysms every day. Three operations, all at the angle of the jaw, inferior dental nerve. Coughing, talking, or chewing excited a paroxysm. About one year ago, strychnine treatment relieved him of a tic which acompanied the neuralgia from the beginning. Had been advised to have ganglion removed, and was skeptical of any measure less radical.

March 21st, injection for the superior maxillary and for the inferior maxillary divisions. The injection caused referred pain to the area of distribution-alongside nose, over terred pain to the area of distribution—alongside loss, malar bone, in tongue, and in lower jaw—immediately followed by analgesia. March 25th, no paroxysms since injection, but still had a constant burning pain. Second injection for the second and third divisions caused characteristic pain in area of distribution, followed by analgesia.

March 28th a third injection was given for the second and third divisions, and on April 1st patient reported that, while there were no more paroxysms, he still had a constant pain fourth injection. April 4th patient reported much reliet and was pleased and encouraged. April 8th relief continned; fifth injection. April 18th, almost entirely free from pain. April 22d, a mild paroxysm to-day; sixth injection. The needle evidently touched the nerves, as the patient cried out that he felt pain in the upper teeth and gums when needle was shoved home for the second division, and in the lower lip and lower jaw for the third division. May 5th, some little pain when chewing. Food retained between left cheeks and gums (analgesia). June 3d, still slight pain when chewing; seventh injection, third division only. June 13th, slight pain in mucous membrane of left check; ulcer size of a dime where mucous membrane of cheek was in contact with a jagged molar tooth of lower jaw; referred

to dentist to have tooth extracted.

Case IX.—J. M. Male. Age fifty-two. Laborer. Patient of Dr. W. B. Thompson. Painful area on right side from upper lip to eye and to temple. Paroxysms every from upper lip to eye and to temple. Faroxysms every two minutes. Laughing, chewing, or touching side of face excited paroxysm. Neuralgia of four years' duration. Two years ago avulsion of infraorbital nerve gave patient relicf for one year. April 1st, injection for the superior maxillary and for the inferior maxillary divisions, without the usual pain referred to the area of distribution, but immediately followed by analgesia of the cheek and half of the tongue. April 4th, patient reported no pain whatever, with tongue. April 4th, patient reported no pain whatever, with the exception of two or three slight twinges in upper lip since injection. Laughing, chewing, or touching side of face no longer excited a paroxysm. Patient much pleased. Case X.—F. H. J. Male. Age seventy-seven. Patient of Dr. D. S. Dougherty. Patient had suffered the agonies

of a severe trifacial neuralgia for forty-seven years. He had consulted many physicians, visiting Europe twice in his search for relief, and had often contemplated suicide as a means of escape from his suffering. Constant pain in the superior and inferior maxillary areas, with severe parox-ysms every hour or oftener. Chewing, talking, or touching side of face excited a paroxysm. He dreaded washing his face or shaving, and had his food prepared so that it did not require chewing. Took a large dose of whiskey and one or two half grain tablets of morphine every night to procure sleep. Bowels constipated. Poor appetite. Frequently nauseated since he began to take morphine. Tongue coated and dry. Pulse 92 and irregular. Systolic murmur at apex, transmitted to left. Had typhoid at age of twenty, and making about this transmitted. and malaria about thirty years ago.

April 6th, first injection for the superior and for the in-ferior maxillary divisions. Washing side of face preparatory to making injection excited severe paroxysms. tion caused the usual pain referred to the area of distribution, but there was no subsequent analgesia. Patient said tion, but there was no subsequent analgesia. Fatient said the pain of the operation was insignificant. April 12th, partial relief. Had been able to sleep without taking morphine or whiskey. Still had some pain, and had several paroxysms. Second injection with characteristic referred pain, but no analgesia. April 19th, almost complete relief. Patient cheerful, and very much pleased. A few paroxysms since second injection. Combing or pulling mustache excited a paroxysm. Third injection. After this injection injection. cited a paroxysm. Third injection. After this injection pulling mustache failed to excite a paroxysm. Complete freedom from pain for five days, and then a few paroxysms excited by sneezing and blowing nose. May 3d, fourth deep injection and an injection into the infraorbital foramen. From May 3d to June 21st, when patient was last seen, absolute relief.

CASE XI.—J. R. M. Male. Age seventy-four. Referred by Dr. Van Valzah. Severe neuralgia for one month, area affected being the nasolabial fold on left side. Frequent paroxysms. Talking, chewing, or touching face excited a

April 7th, injection for second and for third divisions, April 7th, injection for second and for third divisions, with no referred pain in area of distribution and with no subsequent analgesia. April 10th, patient had no relief whatever. Second injection, the superior maxillary division only being injected. No referred pain. Needle reinserted and another injection given, which caused pain referred to the upper lip, with slight temporary analgesia following. April 12th, neuralgia persisted undiminished. Second injection for third division and third injection for second division with pain referred to cheek, lower jaw, and upper lip, followed by analgesia of cheek. April 13th, patient's daughter reported by releptione that her father had not been daughter reported by telephone that her father had not been relieved and did not wish any further treatment. April 30th, patient's son reported that his father had been com 30th, patient's son reported that his father had been completely relieved, the pain subsiding a day or two after last injection, and that the patient's daughter, who was a Christian Scientist, attributed the relief to Christian Science treatment, and had convinced her father that Christian Science cured him after surgery had failed.

Case XII.—E. J. B. Age thirty. Male. Bookkeeper. Referred by Dr. Freeman. For past year pain in right side

of face, especially alongside nose, with tic. Patient described the pain as constant "drawing," which varied in intensity. No paroxysms. He slept well, and was free from pain only when asleep. Had had a spur removed from right side of nose, medicinal treatment, electricity, and x ray, without relief. Gave history of syphilis. April 8th,

injection for second and for third divisions with pain referred to area of distribution, followed by analgesia of cheek and of half of tongue. Tic ceased immediately after injection. April 11th, no tic and no pain since injection. Right side of face swollen. Numbness in cheek, in teeth,

Right side of race swotten. Numbness in cheek, in teeth, and in half of tongue. Jaw felt stiff. April 17th, numb feeling side of nose. No pain and no tic.

CASE XIII.—G. D. Age twenty-five. Male. Law student. Referred by Dr. Garretson. For past two years had had a "burning, drawing" pain under left eye and extending to lip, with a tic. The pain varied as to intensity, usually began at noon and persisted the rest of the day, being absent in the forenoon. Neither washing the face nor the act of chewing excited pain, but powdering the affected part with talcum caused a "drawing" pain. Had been treated for some months with galvanism and strychnine without much relief. Appetite was good. Slept well. Never had malaria nor syphilis. Neurasthenic.

June 17th, injection for second and for third divisions, with pain referred to lower lip, lower jaw, and side of nose,

with pain referred to lower lip, lower jaw, and side of nose, but not followed by analgesia. June 20th, neither pain nor tic since injection. Left side of face slightly swollen. Jaws felt stiff. June 24th, no pain, but tic had returned. Case XIV.—F. S. Female. Age fifty-nine. Referred by Dr. William Steinach. Duration of neuralgia about eighteen months. Location of pain, left nasolabial fold, upper and lower lip, and both upper and lower gums on left side, and left half of tongue. Sharp, darting pain in cheek and in tongue. Several cheek. Burning pain in cheek and in tongue. Sever paroxysms a day. Sleep disturbed by pain and twitching.

June 20th, injection for superior maxillary and for inferior maxillary division, with pain referred to left half of nose,

maxillary division, with pain reterred to left half of nose, nasolabial fold, lower lip, and lower jaw, followed by slight analgesia. June 24th, complete relief.

CASE XV.—J. R. W. Age thirty-four. Male. Dentist. Referred by Dr. D. E. Hoag. Painful area about the size of a quarter in left temple for past six years. Patient described the pain as a "steady pull, as if nerve was caught in forceps." He was awakened by the pain soon after falling reference and was then unable to sleep until 2 or 4 o'clock in asleep, and was then unable to sleep until 3 or 4 o'clock in the morning. Very little pain during the day. No paroxysms. The pain was often accompanied by nausea, and belching afforded relief. No vomiting. Patient said that after taking a dose of medicine—any one of the many drugs or combinations he had tried-there was a peculiar sensation in the affected area, as if the medicine were at work on the nerve." There seemed to be a psychic element in this case (hysteria). It was certainly not typical, and may not be a case of trifacial neuralgia at all. June 27th, injection for third division, with no referred pain and no subsequent analgesia. Operation very painful. Of our fifteen patients, this was the only one in which the patient moved while the needle was being introduced or the injection given. Patient reported to Dr. Hoag July 1st that he suffered from "shock" for two days after the injection, and that, with the exception of one night, he had had relief

It would seem from a study of the cases reported by the originators of this method abroad, with those reported in this country by Kiliani, Patrick and Hecht, that the deep injection of alcohol for relief of the atrocious pains of trifacial neuralgia is a method to be considered advisable when internal medication has failed, and by all means, it should precede the consideration of surgical attack.

CANCER OF THE RECTUM.

1 , tid. g One Hundred Consecutive Operations for Male near Greath of the Rectum and Seemend

By JAMES P. TUTTLE, M. D.,

June 15th. Parts healing by granulation; some continence, but not satisfactory.

Patient moved and was lost sight of, but I have no doubt

recurrence took place early. CASE LXXV.-May 28, 1905. Mrs. N. R., age twenty-

eight. Family history, negative.

Always healthy until seven years ago, when she was constipated one night, and when she awoke the next morning there was a little pimple on the left side of the rectum; this was extremely painful until two years ago, when the pain ceased. Had an operation seven years ago, when the pimple was first noticed, and another one four years ago; wound closed up after the last operation in about two weeks, and then the patient broke out with pimples all around the anus; these have been scraped time and again. Complained now of great pain in the left side of the anus. Surrounding the anus was a circle about six inches in diameter; there was a bright red, granular ulcer upon an indurated base; this did not seem to involve the deeper The left labia was as large as a goose egg; right tissue. labia slightly swollen; large ulceration in the left groin. Pathological report, squamous epithelioma.

June 1st. Instituted treatment by Professor Robinson's

arsenic method. Professor Robinson carried out same. August 1st. Epithelioma entirely gone, and parts healed The patient, however, was attacked with an acute

August 24th. Patient died of tuberculosis. No recurrence of epithelioma.

CASE LXXVI.-June 21, 1905. Mrs. M. L., age fifty-five. Family history, negative.

Healthy until about a year ago, when she began to have pain in the rectum, which pain had never been severe until about a month ago; patient had never been constipated; had a fluid discharge from the rectum; frequent desire to go to stool; had protrusion from the anus at stool. Appetite good, but is losing weight; had lost no blood. Anus surrounded by hæmorrhoids. From the margin of the anus, extending up five and one half inches, was a large, friable, nodular, carcinomatous mass, constricting the rectum, but leaving easy passage for the index finger. Pathological report, adenocarcinoma

July 28th. Operation. Permanent colostomy, July 28th. Operation. Fermanent colostomy, after author's method; found some glands in the sacral cavity, but none above the promontory of the sacrum. Tumor removed from below; perineal method; drainage and pack-ing introduced. Further history of this case was not kept, but she left the hospital on August 1st, practically well,

and has never been heard from.

CASE LXXVII.—October 23, 1905. Mr. A. S. D., age seventy

Family history, negative

Patient was an old soldier; had typhoid, syphilis, and dysentery, all over thirty years ago. For twenty-five years had enjoyed perfect health. Bowels had been free rather than constipated. Six weeks since had an attack of obstruction, with great griping pain. Finally relieved, and since then had been passing blood and mucus at stool. Armoved three or four times a day. Anus normal. Rectum normal for three inches, at which point was felt a large lobular tumor, completely surrounding the gut and almost obliterating its calibre; slightly movable and hard.

October 28th. After several consultations, it was decided to scrape out and cauterize this growth, instead of doing radical operation. This was done; the growth was more movable under an anæsthetic than was expected; could have been removed with comparatively little shock, except for the question of anæsthetic, which the patient took badly. Tumor was scraped out thoroughly and cauterized by Burns electrocautery. Pathological report of specimen,

spindle celled sarcoma.

November 1st. Patient had considerable trouble making urine, on account of enlarged prostate; but no complica-tions of the rectum beyond free discharge; left hospital in three weeks

January 2, 1906. Barring slight cystitis, patient felt fairly

well, but tumor was rapidly recurring, notwithstanding

recauterization.

April 15th. Peritoneal and thoracic metastasis. April 15th. Peritoneal and thoracic metastasis. May, 1906. Died, apparently from cardiac involvement.

CASE LXXVIII.—Nocember 15, 1905. Mrs. A. D., age sixty-five.

Family history: One sister died of cancer of the stomach;

father died of tumor of some kind.

Patient was perfectly well until three and one half years ago, when she was operated upon for hæmorrhoids; since then had been losing blood, and rectal condition was worse; not much pain until a year ago, when she began having pain when bowels moved; this had continued daily. Was never constipated; now has frequent call to stool, with urgent morning stool. Anus normal. In the rectum, two and one half inches above the anus, was a cauliflowerlike growth, friable, and situated on an indurated base; it surrounded the rectum and extended four and one half inches up; movable; considerable glandular involvement in the sacral cavity.

November 17th. Operation. Perineal method; very lit-tle hæmorrhage; the gut was brought down and all the glands in the sacral cavity were removed; could feel none

in the mesentery higher up.

November 20th. Patient doing well; bowels moved

November 24th. Patient troubled with nausea, coming

on suddenly; much pain in the stomach; no temperature. November 26th. Severe pain in stomach, vomiting large quantities of blood. Collapsed and died: Two hours later, post mortem examination showed myriads of small, round ulters in the stomach one of which had involved a large. ulcers in the stomach, one of which had involved a large blood vessel, causing the hæmorrhage. There was no perforation. The pancreas was the seat of a carcinomatous growth, the size of an English walnut, with large glands running up into the gallbladder.

CASE LXXIX.-March 30, 1905. Mrs. W. H. S., age

Family history, clear.

ramily instory, clear.

Twelve years ago, after a milk diet, patient noticed mucus in stool; the doctor found a growth in the rectum and tried to ligate it off; failed; it was then crushed off and cauterized from time to time. When the patient got up in the morning she passed four or six ounces of thin, watery solution, and frequently during the day. A spongy mass protruded when the bowels moved, reduced spongly. Slight pain when the tumor was caught by the taneously. Slight pain when the tumor was caught by the sphincter. Anus normal. Just inside the sphincter was a growth the size of a quarter, and four and one half inches up half a dozen or more similar growths springing from a broad base; soft and did not bleed much; the sigmoid was normal above these growths. Pathologist's report, adenocarcinoma April 3d. Operated. Extirpation of the affected area, by

continuous suture through cufflike mass pulled down to antis; tumor cut off below suture. Apparently, anterior suture went into the peritonæum in Douglas's cul de sac. April 8th. Pelvic abscess formed above the line of anterior suture; an attempt to drain through the posterior

vaginal route resulted in a rectovaginal fistula.

Patient left the hospital; convalescence un-June 1st.

eventful; soft valvular stricture.

April 3, 1906. Two or three small papillæ recurred, one on the surface of the valvular stricture, one just above the margin of the anus. Removed by specimen forceps and cauterized.

December 1, 1906. Stricture becoming more resilient; no

recurrence

October 18, 1907. Absolutely no recurrence. Patient in better health than for years. Stricture narrow, though a May, 1908. Still well. Stricture causes no inconvenience

CASE LXXX.-May 5, 1905. Mrs. C. V. S., age forty-

Family history: Sister died of tuberculosis; father of tumor of the stomach, and aunt of cancer of the breast.

Patient had an operation performed, complete hysterec tomy, four and one half years ago; after that felt pretty well until about fourteen months ago, when she began to suffer from gastrointestinal disturbances; this improved under treatment. Now suffered from soreness and a constant desire to go to stool; discharge of mucus; and attacks of griping pain following a discharge of clear mucus.

Bowels irregular. Anus normal. Rectum normal up to one inch, where a small, hard tumor is felt, confined to the left posterior quadrant. Pathological report, adenocarcinoma.

May 12th. After one week's preparation, salts, liquid diet, beta naphthol, and peroxide irrigations, removed the growth by perineal excision. Removed two and one half inches. Complete suture, no drainage.

May 20th. Union, except on anterior quadrant. Infection shallow, very little pus.

May 24th. Granulation well established.

June 1st. Patient well.

December, 1907. Have not seen her, but heard that she is still well.

CASE LXXXI.-October 28, 1905. Mrs. I. R., age sixty-

Had an operation for uterine fibroid fifteen years ago four years later had a second operation for the removal of About six months ago began to notice a discharge of blood and mucus from bowels. Constipated for charge of blood and mucus from lowers. Consupered myears, slight indigestion. Now has alternating diarrhea and constipation. Anus normal. A hard, nodular tumor, one and one half inches on the posterior wall of the rectum extending three and one half inches.

November 10th. Perineal excision. Gut brought down

and sutured to anus, posterior drainage.

November 20th. No complications, slight incontinence; drainage wound almost healed

November 20, 1907. Still well.

CASE LXXXII.—November 2, 1906. Mr. W. F., age sixty-two.

Family history, tuberculous. For three months patient noticed a difficulty in obtaining a movement of the bowel, unsatisfied feeling; constipation; aching pain just inside the rectum. No discharge. Anus normal. Rectum normal for two and one half inches up, where it was surrounded by a nodular tumor, chiefly on the left anterior wall; movable; upper limits five and one half inches.

November 12th. Amputation, Kocher's method. Very difficult to surround rectum; urethra wounded; tumor extended up six and one half inches. Superior hæmorrhoidal artery ruptured by assistant pulling too hard on gut, very little hæmorrhage. Periteonæum closed by sutures; could not get a good circulation in the gut; sewed it to the skin in sacral wound; perineal drainage and catheter in the bladder.

November 16th Patient did very well for four days, then suppression of the urine developed, and patient died on the fifth day. No autopsy, but septic infection was probably the cause of death.

CASE LXXXIII.—October 10, 1908. Mr. C. G., age thirty-eight.

Family history, negative.

Operated upon for cancer of the rectum two years ago.

Now has pain about the sacrum and pain after the bowels move, more uncomfortable when the bowels are consti-pated. Appetite poor. Discharge of mucus. A large, irregular sacral anus with recurrence in margin. Gut above normal. Posterior rectal glands enlarged.

October 15th. Found recurrence in stump of sacrum, with suppurating cavity on posterior surface of bone;

removed.

October 25th. Parts healing well; patient left the hospital feeling very well.

November 1st. Returned with feeling of bearing down,

and prolapse of the bowel.

November 2d. Loosened up rectum and narrowed anus, suturing the gut walls together and then the skin and buttock over this. Enucleated one small carcinomatous nodulæ.

December I. All healed; continence fairly good. Have not seen patient, but am told he is still well.

CASE LXXXIV.-October 10, 1906. Mr. M. L., age

sixty-four Patient looked pale, haggard, below weight.

bloody stools for many years, but only during the past two years noticed bloody mucus stools; loss of blood and slime; frequent urination, especially at night; after a dis-charge of mucus he felt much better. Flatulence and loss of appetite. Constipated. Dull, aching pain in back. Anus aormal. Four and one half inches up the rectum was a papilloma of the size of a pecan; six and one half inches up was an angulation that the tube would not pass.

October 11th. Removed the papilloma by a snare and cautery. Pathological report, benign papilloma.

December 1st. Symptoms generally improved, but obsti-

pation and discharge of mucus continued, notwithstanding the site of old operation had healed. Examination under anæsthetic, Simon method, discovered carcinoma of the sigmoid, seven and one half to eight inches.

December 4th. Operated with intent to do colostomy. On opening bowel found colon and sigmoid collapsed, small intestine distended by gas; spontaneous lateral anastomosis May, 1507. Patient up and about for four months. He even gained weight, but died from cancer of the liver five

months after operation.

CASE LXXXV.—December 3, 1906. Mr. C. J., age fifty-

Family history, clear.

Alcoholic. Chronic indigestion. Operated for hæmorrhoids in 1900, and had a severe hæmorrhage; had had distress in the rectum ever since. Two operations in the meantime, one three weeks ago; what those were he did not know (patient sent to me as a hopeless case). Grad-ually increasing constipation; frequent call to stool, when

between the ileum and sigmoid at site of tumor; ileum inbetween the fleum and sigmoid at site of tumor; fleum involved in the growth for the length of four inches; liver involved. Resected ileum, end to end anastomosis, Murphy button; did colostomy (Wier); loosened section of ileum and sigmoid involved, and passed them down into the pelvis; closed the peritoneal floor and the abdominal wound, and took out the growth through perineal method; time two and one querter beauty.

time, two and one quarter hours.

December 30th. Patient stood the operation well; recovered the button on the fifteenth day. Artificial anus

nothing was passed but blood and mucus. Constant heavy, aching pain in the back and rectum, worse at night. Discharge of bloody slime. Anus normal. Slightly nodular, friable growth in the rectum, began one and one half inches above the anus, extended three inches; was movable and admitted the finger easily; bled on touch.

Patient prepared for an operation, purgatives, liquid

diet, beta naphthol.

December 10th. Extirpation, perineal method. Tied off middle hamorrhoidal arteries: excised part of prostate; removed six and one half inches and brought the gut

down; sutured musculature to gut and mucous membrane to skin. Posterior anal drainage; obliterated posterior dead space by perisacral sutures.

dead space by persacral stitutes.

December 12th. Practically no oozing or other complications. Temperature, 99° F.; pulse, 85; felt well.

December 30th. Left hospital entirely healed and per-

fectly well. April, 1908. No recurrence; feels well; has gained thirty

pounds. CASE LXXXVI.—December 22, 1906. Mr. W. E., age

Family history, negative.

the sigmoid and made artificial anus; closed peritoneal floor; cut off gut by electroangiotribe; tied superior hæmorrhoidal arteries; removed tumor by perineal method; very little hæmorrhage. Patient returned to ward, pulse, 104, soft, and regular.

December 29th. Suppression of urine developed, and patient died to-day; autopsy not permitted.

CASE LXXXVII.—November 7, 1905. Mr. G. H. E., age

fifty-seven. Always had trouble with his stomach; very nervous; had an operation for hæmorrhoids five months ago. For the past six months had had a constant desire to go to stool

Personal history, clear up to eighteen months ago, when he had periodic bleeding from the rectum; this became more and more frequent until in the last three months it had been almost constant. Discharge of mucus and blood in the been almost constant. Discharge of nucus and blood in the morning stool; bowels moved frequently. Great loss of weight. Smarting, aching pain almost constantly. Anus normal. Two and one half inches up the rectum was a large, craterlike carcinoma, covering the entire circumference; movable, but upper limits could not be felt by finger; no glands enlarged.

December 27th. Operation. Combined method. Cut off

without being satisfied, a feeling as if there was something more to come away; soreness over the transverse colon and sigmoid; urgent morning stool; bowels constipated; slight discharge of blood and mucus at stool, also protrusion of mucous membrane. Prolapse of mucous membrane on the right side of rectum; small tumor constricting the rectum, seven inches up, seen through protoscope. Diag-nosis scouted by patient and his physician. Returned home.

January 15, 1906. Has had examination under ether and section removed. Tumor proved to be adenocarcinoma; glands involved; tumor on the right border of liver.

Bowels grow more difficult to move. Lump at the right corner of the liver felt like apex of kidney, movable, but attached.

January 22d. Laparotomy. Lump found to be pedunculated tumor of the liver, with marked carcinomatous in-volvement of the organ on its lower border. Fæcal current

side tracked by colorectostomy; drainage. Barring drainage tract, convalescence was January 31st.

uninterrupted; bowels moved the third day, and daily since. The fistulous tract healed, and patient was comfortable for five months, when he died quite suddenly. No autopsy was permitted.

CASE LXXXVIII.—December 22, 1906. Mr. D. H., age fifty-five.

Family and personal history negative.

For two years patient had noticed a discharge of mucus before stool. Bowels were regular, rather soft; no pain; discharge of mucus and blood after stool. Anus normal. Small internal hæmorrhoids in rectum. Four and one half inches up in the left anterior quadrant was a shaggy tumor, nodular, and attached by pedicle over area of one inch.

January 5, 1907. Operated. Kraske's method. Excised portion of gut bearing pedicle, and sewed walls of the gut together; left posterior wound open for drainage. Patho-

logical report, adenocarcinoma.

October, 1907. His physician tells me there is evidence

of recurrence

CASE LXXXIX.-April 25, 1906. Mr. S. J. B., age fifty-

Family history clear, except for tuberculosis in uncle. History of spinal meningitis in 1894, complete recovery. Had dysentery three years ago, continued with intermissions, ten to fifteen stools a day; unsatisfactory defæca-tion; required morphine or other sedatives; burning pain at anus before stool; constant mucopurulent, bloody dis-charge. Ulcerations for three inches up the rectum, in-durated in spots and elevated. Specimen showed beginning malignancy

Operated. Perineal route. Removed three April 28th. and one half inches; sutured musculature to gut and mucous membrane to skin; no glandular involvement

May 3d. Only part of the sutures held, but the drainage of the infected area was good, and the deep spaces did not seem to be infected.

May 15th. Patient felt quite well; small fistulous tract

May 15th. Fatient left quite went, small states still remained. Patient went home.

April 2, 1908. Still well by report.

CASE X.C.—September 20, 1906. Mr. J. C. J., age fifty. Three years ago patient had polypus of rectum removed, no inconvenience; four weeks ago had a second one removed; had secondary hæmorrhage that night, and another one week later from straining. Bowels regular; no pain. External thrombotic hæmorrhoids about anus. Indurated movable mass in the rectum, with granulating top, just to the left of anterior commissure, inside the sphincter; one enlarged gland four inches up.
September 26th. Operated. Perineal method. Five and

one half inches amputated; sacral glands removed; part of the external sphincter removed. Musculature sutured to the gut; sacral dead space closed by perisacral sutures

October 15th. Convalescence uneventful; small infection in outer wound; sacral space perfectly obliterated.

December 1st. Patient left for home, well but not strong.

February I, 1908. No recurrence. Patient well, but had not regained normal strength.

June 1st. Has improved much recently and is now perfectly well.

CASE XCI.-May 31, 1906. Mr. F. M., age forty-five.

Family history, clear.

Had hæmorrhoids injected in 1885 and twice since, the last time eighteen months ago. For three weeks had had throbling and burning at the anus, commenced after stool, and lasted usually from four to six hours; to-day had lasted all day; shooting pain into the testicle and penis. Slight bloody discharge; constant protrusion. Three small protruding hæmorrhoids; on the summit of one a hard, node at ma, the tree of a plit pea was seen. Sigmoid normal

May 31st. Removed protruding painful mass, under

Pathological report, adenocarcinoma cocaine.

June 19th. After proper preparation, amputated the left from previous operation.

August 10th. Patient had infection and several large abscesses, but finally recovered.

January, 1908. Remains perfectly well. CASE XCII.—April 4, 1906.—J. B. S., age forty-one.

A year ago patient was operated upon for ulcer of the rectum, which healed, and then broke down again and never healed. Had artificial anus done in January, and an operation for hernia two weeks later. Could not sit for pain. Large carcinoma involving the deep tissues of the rectum and extending out into the right ischiorectal fossa

over tuberosity; no glands involved.

April 6th. Scraped and cauterized growth.

June 1st. Some relief. Removed large growth from buttock, which interfered with sitting.

July 1st. Great relief from last operation. Cauterized growth again.

January 28, 1907. Had repeated the cauterization three times in the past year. Patient had improved in health, but tumor continued to recur.

Have not heard from him since.

CASE XCIII.—January 6, 1907. Mr. C. T., age twenty. Family history was negative.

Patient had had ear trouble since typhoid fever at nine years of age. Pain and bleeding at stool for the past two months; frequent desire to go to stool, but unsatisfactory. Never constipated. Protrusion and discharge of blood at stool, pain after stool Just in the anal canal was a small, wartlike growth, at the anterior commissure, hard, rough,

but not indurated at base; bled on touch. January 10th. Growth dissected out and base cauterized. Hæmorrhoids taken off with a clamp and cautery. Patho-

logical report, squamous epithelioma.

April 10, 1908. Perfectly well. CASE XCIV.—October 27, 1907. Mrs. M. C., age thirtyeight.

Family history, negative.

Fatient had hard labor three years ago. Four months ago began to lose blood at stool, and had alternating diarrhea and constipation. Operated for hamorrhoids one month ago, no benefit.

Present condition rather feeble; not much pain, except a bearing down feeling in the rec tum; lost blood and mucus every day. Anus practically normal. Rectum three and one half inches up showed a friable, nodular tumor, entirely surrounding the gut and extending three and one half to four inches. Enlarged glands posteriorly.

November 12, 1907. Operation (under hyoscine and morphine preliminary, and chloroform anæsthetic). Perineal method. Tied middle hæmorrhoidal arteries; removed fifteen inches of the gut before we ceased to find enlarged glands; sewed up peritonæum before cutting off gut. Sewed musculature to gut, then cut off latter outside the wound, and sutured mucous membrane to skin margin. Left in posterior drainage.

November 20th. Progressing well. Had chill last night; temperature 100° F. to-day. I could not find any tender spot, and the patient had no pain.

November 22d. Typical typhoid look and temperature, but to-day a discharge of pus came down through the pos terior drainage, and temperature dropped. Was never able

to find abscess by palpitation.

January 10, 1908. Patient had been home six weeks, doing well. No recurrence, but another abscess like the

first developed to-day.

February 4th. Noticed a small nodule in the vaginal wall, with several enlarged glands; removed and scraped out posterior fistulous tract. Parts feel all right.

February 20th. Patient feeling better. Pathological re-

port showed nodules to be adenocarcinoma; glands were

simply inflammatory.

April 3d. After a month's absence from the city, I find rapid and unmistakable recurrences at the margin of the anus and in the posterior rectal glands, as high up as the finger will reach. Patient has practically no pain, loses no blood; is not gaining in flesh or strength.

May 25th. No further operations; patient rapidly losing

ground.

June 5th Patient died. Case XCV.—October 3, 1907. Mr. G. T. H., age sixtycight

Bowels had been regular up to four or five months ago since which time he had to take medicine; had noticed excessive gas in intestines. Morning diarrhœa; could not control stool. Bowels moved from six to twelve times a

day, accompanied by gas and slime. Difficulty in passing urine; constant dull pain, acute after stool. Anus normal. Condylomatous malignant mass three and one half inches up the rectum and extending two and one half inches; movable; healthy mucous membrane above and below; no glandular enlargement that could be felt; admitted sigmoidoscope

October 8th. Operated. Bone flap method, through orthografies seement; anus sewed up before beginning operation; very little difficulty in bringing gut down; closed anterior rent in peritonæum before opening the bowel; cut gut off below the tumor with Pryor's electric angeiotribe; mucous membrane of anus everted; sigmoid dragged through anus and sutured outside; no great ten-sion; some hæmorrhage in the region of prostate, which required packing; anchoring suture through mesorectum carried around the lower end of the sacrum and tied over a gauze pad, thus closing the dead space in the hollow of

November 1st. No complications of importance except exaccerbation of old Bright's disease; patient did not regain strength. Boneflap united perfectly; small fistula

persists. December 1st. Wound practically well; bowels moved normally, but fistula persisted, and although he was up and about he gained very slowly. Left hospital for home

March 31, 1908. Patient died to-day, without recurrence; "simply wore out."

CASE XCVI.-December 30, 1907. Mr. T. M., age forty-

seven.

Family and personal history, clear.

About a year ago patient first noticed protrusion and bleeding at stool. Had always been constipated. Operated for piles in April, 1907; had curettage or something done for stricture which was discovered at the time. "Mucus and white deposit in urine." Aching, throbbing pain at stool, followed by a discharge of mucus. Anus normal, not even a sign of previous operation for piles. (Was any ever done? or was this another case of diagnosis after the patient was on the operating table?) About three inches up the rectum a hard, cauliflowerlike growth entirely surrounded the activation of the condensation of the condensati rounded the gut, and above this was a second growth, which felt papillomatous. Odor unmistakably malignant. Proctoscope could be carried through constricture; eight and one

January 3, 1908. Perineal operation. Nine and one half inches removed. Tied off middle hæmorrhoidal arteries; anal musculature sutured around gut; mucous membrane sutured to perineal skin; no hæmorrhage or shock. Patho-

logical report, adenocarcinoma.

January 17th. Introduced Coley injections.
January 24th. Left hospital, perfectly well.

May 25, 1908. Patient perfectly well and following his

trade of engineering CASE XCVII.—February 10, 1908. Mrs. M. A., age fifty-

Patient had a habit of taking laxatives. Passage of mucus and blood only in the last two months. Frequent desire to go to stool without result, and with much gas. Anus normal. Rectum smooth for three inches up, where a circular, craterlike nodular growth extends two inches; finger easily admitted; movable; no glands felt; vaginal

walls free. February 21st. Operation. Perineal excision. Removed six and one half inches; no complications; time, fifty-five minutes; sutured musculature to the gut and mucous mem-

brane to the skin; long incision up alongside of the occyx for drainage.

March 1st. Patient progressed most favorably; not a

complication.

April 5th. Felt perfectly well; posterior anal wound

June 1st. No sign of recurrence.

CASE XCVIII.—September 8, 1905, Mr. C. C., age fifty-eight.

Patient had been laid up for eight months, following a perirectal abscess in 1897; had been pretty well since, except for slight incontinence and occasional attacks of proc-titis with passage of blood and mucus. No pain. Bowels regular, moving twice a day; if soft, small clots of blood; if hard, streaked with blood. No muscle on one side of the

Hæmorrhoids opposite angular opening in the rectum. Small granulation, from which blood came. Refused treatment.

January 17, 1908. Called in consultation by Dr. Bull. Patient had had prolonged treatment for boggy condition of the rectum over prostate; some two months since began to pass blood and mucus; frequent desire to go to stool; no loss of flesh; irritation of the bladder; almost complete incontinence, as noted in 1905. Ulcer one and one half inches up, to the left of the prostate, in the anterior wall; sub-mucous fistulous tract running upward about one and one half inches, pocket at the lower end of ulcer.

January 19th. Tract laid open by Dr. Bull. Section of

tissues made and found benign.

February 5th. Fistula and ulceration almost healed; there appears to be bloody mucus coming down from above; acute flexure of the sigmoid, so that tube is stopped six inches above the anus. Given nitrous oxide gas and par-tially introduced hand into the rectum, so as to feel a growth just above the flexure; hard and nodular, constricting the bowel so that the index finger could not be introduced; upper limits of the tumor beyond reach, but mov-able. Specimen removed with specimen forceps. Pathological report, adenocarcinoma.

February 12th. Operation. Combined excision. Removed eight inches of the gut; attempt to take the tumor out through posterior anal incision a failure; it was finally taken out through the abdominal wound; rectum everted; gut invaginated; end to end suture made; all held down by

sutures to the skin.

February 13th. Patient suffering from shock; given eserine and adrenalin in full doses.

February 19th. Patient doing well; temperature 99.5 F., pulse 105. February 20th. Dressing removed. Infection of the

abdominal wall does not extend below the external fascia. Dressed with balsam Peru and castor oil. Bowels move daily by means of laxatives. Some fæcal discharge through posterior drainage.

March 1st. Abdominal wound granulating well; pulse and temperature normal; fæcal discharge through fistula

decreasing.

May 1st. Patient left for home March 15th. Has visited my office from time to time; fistula remains open, but no faceal matter passes through. inches up, at point of suture. Patient in fine physical condition except for incontinence; mentally depressed over this

August 20th. Stricture sufficiently open to admit index finger easily; is getting softer. Patient gaining flesh.

CASE XCIX.-February 13, 1905. Mrs. B. G., age forty-

Family history, negative.

Patient had had eight difficult labors. Difficulty in moving the bowels for the past two years; flatulence and vomiting; marked pain in the lower end of the rectum. Operated for stricture of the rectum nine months ago. Frequent stools, with blood and mucus. Hard, nodular stricture of the rectum two inches up, extending one and one half

February 18th. Perineal excision, modified Quenu. Difrebruary in dissection, owing to previous operation; gut finally brought down; musculature sutured to gut; mucous membrane to skin. Pathological report, adenocarcinoma. February 21st. Stitches all held except two or three in

the anterior commissure; some granulation there; slightdischarge from posterior drainage.

March 10th. Slight incontinence, but improving. Patient

left the hospital.

November, 1905. Continence fairly good; no recurrence. CASE C .- December 3, 1907. Mr. G. P. C., age fifty-

Early history of quinsy. Long history of constipation. Typhoid fever, not worse afterwards. Eight months ago had acute obstipation, which cathartics did not relieve; had slight nausea and vomiting, four or six days before a movement was induced; stool dry and lumpy, then watery; since then had had one or two attacks, but not so bad. Flatulence, which he could not pass downward. No movement except from cathartics, a desire but no results, scant discharge of mucus. Anus normal. Rectum normal; two or three hard lumps anterior to the left in Douglas's cul-desac, felt through the walls of the rectum like masses of

fæcal matter in a prolapsed loop of the sigmoid. Tube entered nine inches, and encountered a flexure which was impossible to pass.

December 4th. Oil and high irrigations, peroxide and other enemas gave no fesults; alum enemas ordered.

December 5th. No result, not even gas. Patient much distended, pulse rapid. Operated at 2 p. m. Abdomen incised outside of the left rectus; guts so distended could not keep them in; finally drew tumor of sigmoid out of wound, and resected seven inches, making artificial anus. Could not return guts owing to distention; had to make a second opening in the transverse colon and put in Paul tube.

December 6th. Patient doing fairly well; fæcal matter coming from artificial anus and from tube. Tympanites

rapidly disappearing.

December 7th. No change.

December 9th. Removed Paul tube. Fæcal matter passing freely by artificial anus.

December 12th. No complications; patient doing well.
December 22d. Patient progressed well until to-day;
was sitting up in bed taking a glass of wine, when he said,
"Oh!" dropped the glass, and fell over dead. No autopsy was permitted, but we assume the cause of death was embolism.

Conclusions.

1st. Extirpation is the only method that affords any hope of life or prolonged comfort to sufferers

from cancer of the sigmoid and rectum.

2d. Periodical, systematic, and thorough local examination of the rectum in all cases afflicted with irregular intestinal action, or symptoms pointing to disorders of the alimentary tract, is the only safeguard against these growths attaining an inop-

erable state before discovery.

3d. The only absolute contraindications to removal are immobility and involvement of the liver. 4th. The operation of amputation, by the peri-

neal route, is feasible in nearly all cases of rectal cancer, and should be the operation of choice whenever the combined or abdominal operations are not

5th. The operations on early recurrences are not

usually successful.

6th. Old age, with good physical condition, offers exceptionally good prognosis in these cases, and, contrary to expectation, the very young may be cured of the disease.

7th. Although our methods are far from being as successful as we would wish, they are still worthy of pursuing and improving.

42 West Fiftieth Street.

THE LEUCOCYTE COUNT IN ABDOMINAL SURGERY.

An Analysis of Fifty Cases.*

New York,

V. A. Strame, Surgeon. St. Luke's and Bellevue Hospitals: Instructor in Surgery, New York University and Bellevue Medical College.

The changes in the white corpuscles of the blood in the presence of acute inflammatory processes have been made use of by the surgeon as an aid to diagnosis ever since Sadler (1) in 1892 asserted that leucocytosis was generally, though not invariably, present in diseases attended with an exudate of any kind, excepting in tuberculosis. Cabot (2), Gries

(3), Bloodgood (4), Joy and Wright (5), Cazin and Gross (6), French (7), and others wrote on this subject, but they concerned themselves only with the total leucocyte count. This as a means of determining the presence of pus or gangrene showed such a large percentage of error that it fell into disrepute, and Sondern (8) considers the total leucocyte count only as an indication of body resistance, and therefore of no value when considered alone as a guide to the determination of the intensity of the pathological lesion.

However, there are still a number of surgeons who place considerable reliance on the total leucocyte count. Deaver (9), in an article published about a year ago, gives the results of the total count in one hundred cases of appendicitis with abscess, in which he found a leucocytosis below 1,000 in ten cases, between 10,000 and 20,000 in sixty-one cases, between 20,000 and 30,000 in twenty-three cases, and over 30,000 in six cases. In an analysis of the comparative leucocytosis of suppurative abdominal lesions, he gives an average of 17,760 in appendicitis with abscess, 13,000 in pyosalpinx, and 9,000 in diseases of the biliary tract. He quotes statistics of Dr. Ghrinsky in one hundred cases of appendicitis, who found an average of 11,246 when the disease was confined to the appendix, 18,500 in cases with abscess, and 8,960 in cases of chronic appendicitis.

Jennings (10) writes that the significance of the total leucocyte count and the distinctive count (to be considered later) are the same, and considers that the theory of the polynuclear count being of more importance than the total count is "unsound." He quotes Kelly, who writes: "In appendicitis early in the disease a rising leucocytosis is an indication for operation. Later, with abscess formation, no reliance can be placed on the leucocyte count." Also Da Costa, who states: "Appendicitis should never be ruled out because leucocytosis is absent. Nor should moderate leucocytosis be considered an indication

of the severity of the lesion." Kothe (11) in a study of the total leucocyte count in appendicitis, reaches his conclusions as to the nature of the lesion and the prognosis by the relation of the temperature and pulse rate to the leucocytosis. He figures that a temperature of 37.9° C., pulse 96, and leucocytosis of 14,000 indicate catarrhal appendicitis. Temperature 38.2° C., pulse 116, leucocytosis 20,000, indicate severe inflammation in the appendix, but as a rule localized. Temperature 38.5° C., pulse 122, leucocytosis 30,000 indicate more or less spreading peritonitis, but with a good prognosis. Higher temperature and pulse rate with lower leucocytosis—e. g., 18,000, general peritonitis with doubtful prognosis. Quickly falling leucocytosis, with sustained elevation of temperature and pulse rate, indicates a bad prognosis. He calls attention to an ante mortem leucocytosis, and also states that in gallbladder disease the leucocytes are little or not at all increased in number. (See Cases XXX and XXXI.)

Sondern, in the article previously mentioned, in which he discredited the value of the total leucocyte count as the result of a large number of blood examinations (1,415) in surgical cases, called atten-

[&]quot;Read before the semiannual meeting of the Queens-Nassau Medi-

tion to the proportionate changes in the polynuclear cells in purulent and gangrenous conditions. a result of his studies he concludes: "A relative percentage of polynuclear cells below 70 with an inflammatory leucocytosis of any degree excludes the presence of gangrene or pus, at the time the examination is made. . . . In adults a purulent exudate or gangrenous process is decidedly uncommon with less than eighty per cent. of polynuclear cells, and the probability of their presence increases with this percentage. . . . Eighty-five per cent. or over I have never seen without a purulent exudate or gangrenous process irrespective of the leucocyte Since the publication of his article a number of others have been written with favorable reports as to its value. Sondern himself has repeated his conclusions on numerous occasions, and in a recent paper has met the objections of those whose opinions were unfavorable, by first questioning the accuracy of the count in those cases with contradictory findings (made by untrained internes), and also by the theory that in a few cases there is but a slight absorption of the toxines and due to a low vitality or poor circulation; one drop of blood from the ear does not represent the true condition of the patient. He admits, however, that the differential count in children is less reliable than in adults.

In agreement with the views of Sondern, Mc-Kernon (12), writing on The Blood Examination in Otology, considers "the differential count confirmatory in clear cases and of value to complete diagnosis in doubtful cases"; while Taylor, writing on The Blood Examination in Gynæcology, writes: "In acute cases both the total count and the polynuclear cells were increased in proportion to the severity of the disease, but should be taken with the other symptoms." In the discussion of the above papers, Lilienthal (13) is quoted as saying that "he had come to the conclusion that in determining whether to operate or not, the blood count could be entirely disregarded." He cites three cases with

negative or contradictory findings.

While agreeing with the accuracy of Sondern's conclusions in most instances, Gibson (14), in an analysis of about 200 cases, cites a considerable number of exceptions to all of his rules, and his paper was written with the purpose of proving that a more valuable means of determining the severity of the lesion lay in the relation of the total and differential count. He devised a chart, on which he assumed the limit of the normal leucocyte count to be 10,000, while the equivalent, polynuclear percentage was 75, and that normally if the inflammatory process and the resistance were equal the polynuclear percentage would rise I per cent. with each 1,000 of the total leucocyte count. These he called units, and the relative disproportion between polynuclear percentage and the total count, as shown by his chart, he considers of great importance in diagnosis and prognosis. He writes:

Speaking generally and with considerable reserve, if the line connecting the levels of the leucocyte count and the polynuclear count run pretty nearly horizontal, whether up or down only two or four units difference, it indicates that whether severe or not the lesion is well borne and therefore of good prognosis. . . Lines running upward from the leucocyte side toward the polynuclear side indi-

cate in general a rather severe lesion and less resistance. If the interval between the two points is considerable, say ten or more units, we are quite sure to have a severe lesion. The majority (about two thirds) of total cases of all kinds show a rising line, and in such a condition as appendicitis fatal cases have all a rising line. . . . In appendicitis all the severer lesions, as those with gangrene of the appendix or progresive peritonitis, and all the fatal cases showed a or progressive peritonitis, and all the ratal cases showed a rising line on the standard chart, while all the cases indicated by a falling line were of distinctly mild types, such as well defined "safe" abscesses with little febrile or constitutional disturbance. The negative findings showing no relative increase, or even an actual decrease of the proportion of polynuclear cells, while of less value, show with rare exceptions the absence of the severer forms of in-

Since the publication of Gibson's article the writer has found nothing published confirmatory or otherwise of his conclusions, although his suggestions are mentioned in articles by Wile (15) and by Shaw (16), and Albrecht, in an analysis of 164 gynæcological cases, places great diagnostic value on the relation between the polynuclear and total count.

Other methods of indicating the presence or absence of pus or gangrene, and of determining prognosis, have been suggested by various writers. Holmes (19) judges the body resistance by the small lymphocytes, and Albrecht states "when the number of lymphocytes is considerably below normal the infection may be regarded as especially serious."

Iodophilia, or the iodine reaction of leucocytes, seemed for a time to be of value, but the reaction does not appear to be proportionate to the amount of pus present, and the degree of reaction is difficult to determine with any accuracy. Sudanophilia, or the staining of the fat droplets, present in leucocytes in inflammation, a deep red with Soudan iii, has been studied by de Marchis (20). The result of an examination in 117 cases showed it to be negative in cases of encysted pus, as in salpingitis and pelvic abscess, and the reaction was present after fractures, or a meal containing much fat. It is also stated that the presence of over one per cent. of eosinophiles is opposed to the presence of pus except in chronic cases, and returning eosinophiles indicate convalescence. Boswell (21) has written on this subject with a report of nine cases, and Albrecht considers the presence or absence, increase or decrease of eosinophiles and mast cells of aid to diagnosis and prognosis.

All these theories have been cited, and in many instances rather lengthy quotations have been made with the purpose of indicating the contradictions and differences of opinion existing among those writing on the subject. The writer has made use of the total leucocyte count for nine years, the differential count for over two years, and since the publication of Gibson's article his method of unit difference as an aid to diagnosis and prognosis, and particularly as a means of determining the need of immediate operation, but a series of four cases (Cases IV. V, XXV, and XXVII), all occurring within a short period of time, in which the blood examination showed a considerable variance with what might have been expected, made him determine to keep a record of all the acute abdominal conditions coming under his observation since then. These cases, 50 in number, occurred in the service

of Dr. B. F. Curtis, at St. Luke's Hospital, and were operated on by or under the observation of Dr. Curtis or the writer. The blood counts were made by the pathological staff of the hospital, and there is every reason to believe them accurate.

The record of the fifty cases selected is not sufficient to be of any great statistical value, but it proved to be of considerable interest, and while the conclusions of many writers were borne out, even in so small a number of cases, many exceptions were found. The cases have been grouped according to the, variety of pathological lesions and the organs involved, and while an average has been made, it has not been done with the view of establishing statistics, as the numbers were small and the range of variation large, but merely for purposes of com-

parison.

First, as to the total count. This is fairly consistent with what one would expect to find: 17,800 in the ten cases of general and spreading peritonitis; 21,950 in the nine cases of gangrenous appendicitis, with or without abscess; and 12,800 in the cases of acute appendicitis subsiding without operation. In the acute pelvic cases, the average leucocytosis was 25,100. The blood counts of a number of cases of chronic appendicitis and chronic salpingitis were made, but as they showed nothing of interest they have been omitted from this series. The exceptional cases were Case IV, in which there was a leucocytosis of only 7,000 as a result of gangrene of the appendix and cæcum, with severe general peritonitis. This patient showed no reaction and died shortly after operation. Cases V, VI, and VIII showed only 12,900, 11,200, and 12,500 respectively in the presence of spreading peritonitis. Patients of Cases V and VI recovered, while patient of Case VIII died. Case XXI was of interest, as, in the presence of 28,200 leucocytes the appendicitis subsided without operation, and three days later his leucocytes numbered only 7,900. It is also of interest to note the high total count in the acute pelvic cases, a large tuboovarian abscess, Case XL, showing a leucocytosis of 40,800. A careful analysis, then, of the total count in the whole list of cases, in view of the extreme variations found, would seem to indicate, while the leucocytes indicated in general the presence of pus or gangrene, it could not be taken by any means as a measure of the infection present.

As to the value of the total count as a means of determining resistance to infection, three patients suffering from appendicitis with general peritonitis, died within twenty-four hours after operation, one with 7,000 leucocytes (Case IV), one with 18,400 (Case II), and one with 12,500 (Case VIII). Of the other two fatal cases (with the exception of the two typhoid perforations), one patient (Case I) died eight days after operation, of intestinal obstruction. His leucocytes were 19,700 and he showed good resistance. The other patient died of intestinal obstruction, thirty days after operation, and while she had 14,800 leucocytes before operation, she showed no resistance to the infection, which originated around the cæcum three years after an operation for appendicitis, the culture from the pus being sterile. Another patient, pelvic case (Case XXXIV), with 30,000 leucocytes before operation, is still in the wards four months after a posterior colpotomy for pelvic abscess, and is still having a raised temperature, and showing little resistance to her infection.

And while it would appear that the leucocytosis is in some degree a measure of resistance, an examination of the appended list would seem to show that the time the infection has existed is also an element in developing the resistance and the number of leucocytes, as the acute peritonitis cases which were operated on early showed a lower average than the appendicular abscess cases, and these in turn a lower count than the pelvic cases, in which the lesions had existed a longer time before operation

was performed.

Taken as a whole, the differential count is fairly consistent with the rules laid down by Sondern, but here also are found several exceptions. The average for the peritonitis cases was 82.5 per cent., but this was lowered by three exceptional cases (IV, V, and VIII), with 72, 77, and 65 per cent. It is interesting to note that in Case IV the polynuclear count was by no means an indication of the severity of the lesion, while Case VIII, that of a boy three years old, with appendicitis and spreading peritonitis, shows the unreliability of the polynuclear count in children. The highest percentage, 91 per cent. in the appendix cases (Case XVIII), was one in which the appendix was gangrenous at the tip, but in which no abscess was present. Case XX was of interest as an exception, as, with 87.5 per cent. there was a greatly thickened and inflamed appendix, but no pus or gangrene was present, although the disease was of ten days' duration. Case XXV was also an interesting exception, as she showed 90 per cent. of polynuclears with a diagnosis of intestinal toxæmia, which convalesced in forty-eight hours with catharsis. Case XXI showed 88 per cent. of polynuclears (with an acute appendicitis), which, according to Sondern, always indicates pus or gangrene, but subsided in a few days without operation.

The acute pelvic cases averaged 83 per cent., and with one exception were quite consistent with the operative findings. The one exception was Case XL, a woman with a large tuboovarian abscess, who, with 40.000 leucocytes, had only 71 per cent. of polynuclear cells. She showed good resistance and was never very sick, while in a case of cellulitis of the broad ligament, with 23.500 leucocytes and 92 per cent. of polynuclears, the patient had a temperature of almost 107° F, both before and after operation, and later was attacked with a severe pyæmia with an abscess of the lung, and only recovered after being desperately ill for several weeks.

In the five infected abortion cases both the total and a differential count showed extreme variation—7,500 (Case XLIX) to 23,900 (Case XLVI), and 64 per cent. (Case L) to 93 per cent. (Case XLVI) case XLVI seemed to be sicker than either Case XLIX or L, but as they all subsided in a few days with treatment, it is difficult to determine just what the blood count indicated.

The method of determining the diagnosis and prognosis by the relation of the total and the differential count, which was suggested as of greater

value than either taken alone, shows in the appended series of cases a greater variation than if dependence were placed on the differential count alone, and almost as much variation as does the total count Four of the fatal cases (I, II, IV, and XXVII) showed very little variation either + or - on the "standard chart," while Case VIII, a child, showed - 12. The ten peritonitis cases averaged o, which would be represented by a horizontal line. In two children, aged six and seven years (Cases VI and VII), with spreading peritonitis, one showed + 14, the other - 14. In Case XX, in which there was no pus or gangrene, although the appendicitis had existed for ten days, the standard chart showed + 13; while a case of intestinal fermentation showed + 9. One large walled of abscess (Case XIV) showed +8, while a similar condition in another patient (Case XIII) showed - 18. In two of the gangrenous appendix cases without perforation or abscess, one (Case XVIII) showed -7 and -4, while the other (Case XIX) showed +5 and +4. Two counts were made in each case. Case XXI. while the patient was severely sick, showed -5, and three days later, when convalescent, showed + 10. Case XXII, one of appendicitis convalescing without operation, showed +8. In the septic endometritis cases following abortion it was quite consistent with the apparent condition of the patients. In the general pelvic cases, however, it showed great range, one case of tuboovarian abscess (Case XL) showing - 35.

Since the writing of this paper Noehren, in the Annals of Surgery, February, 1908, in an article on The Value of the Differential Leucocyte Count in Acute Appendicitis, analyzes sixty-two cases, and found a rising line in twenty-three, horizontal line in six, and falling line in twenty-three, and concludes the method to be less valuable than if reliance was placed on the differential count alone.

In the consideration of the general abdominal cases, the typhoid perforation case (Case XXXVIII) was of interest, as it showed a gradually rising total count, from 3,800 to 4,700, with a still greater proportional polynuclear count, from 60 to 73 per cent. after the perforation, four counts being made in eleven hours before an acute peritonitis had developed, while Case XXXVII, with 26,000 and 83 per cent., illustrated the blood picture of a severe general peritonitis, forty-eight hours after the perforation of a typhoid ulcer. Cases XXIX and XLV showed the influence of hæmorrhage into the peritoneal cavity in causing a rise of both total and polynuclear count, just as in suppurative conditions. Case XXVIII, a child thirteen months old, with an intestinal obstruction from bands and adhesions two months after operation for intussusception, is of interest as an example of the very little value of the blood count in young children, as, notwithstanding a beginning peritonitis, his distinctive count was 64. and his line on the standard chart showed -26.

Both of the kidney cases showed high total and differential counts, while the unit differences were only + 1 and 0. Of the gallbladder cases, one (Case XXX) showed 22.600 with 87 per cent., the other (Case XXXI) 11.800 with 05 per cent., although, as stated previously in this article, diseases of the biliary tract are supposed not to give, as a

rule, high blood counts. Case XXXI was of interest as, notwithstanding the high polynuclear count, 95 per cent., which Sondern considers of such bad prognosis, she made a perfect recovery after cholecystectomy.

Finally, what deductions can be drawn from these facts? Is the margin of error sufficient to invalidate the value of the leucocyte count entirely, as has been asserted by some? It would appear not. Great variations do appear in both counts. In regard to the total count, the leucocytes are certainly increased in suppurative and gangrenous conditions as well as those in which there is an effusion of blood into the peritoneal cavity, but it seems impossible to state that any given number indicates pus or gangrene. And while the higher counts do, in most instances, indicate pus or gangrene, it must be borne in mind that low counts do not rule either or both out. In the main, Sondern's conclusions as to the differential count are borne out by the appended series of cases, but with a considerable number of exceptions.

Concerning the comparative value of the total and differential count, in a large majority of cases both showed an elevation almost equally relative to the pathological condition; and in several of the cases, as IV, XXI, XXV, and XXXIII, where the total count was at fault, the differential count was equally misleading. And as the differential count seems to follow the total count in such a large proportion of cases, it seems questionable whether the statement that the latter is of no value except as an indication of body resistance, is correct. Also the differential count would appear to show somewhat less variation than the total count, and seems to be of greater value than the latter, particularly as we have some

definite limits, such as those set by Sondern; but

here also it is to be repeated that in the writer's

experience there is a considerable margin of error.

However, the record of the pulse and temperature, in several cases listed in the accompanying table, also shows the uncertainty of the body reaction indicating the extent of the pathological lesion, and as one would not think of disregarding the pulse and temperature in making a diagnosis, so should one consider both the total and differential count as part of the symptom complex or clinical picture of the case to be considered. After all, it is the combination of symptoms which must be considered in any abdominal case. The persistence of vomiting, the amount of rigidity or pain, the sudden letting up of pain with persistence of other bad symptoms, indicating gangrene with perforation and relief of tension, the abdominal facies, the poisoned look of the patient, the continued or rising pulse and temperature, all these symptoms indicate in the clear case the need of operation. But in the case seen early, where the diagnosis is not clear, where one feels the danger of waiting to see whether the unfavorable symptoms continue or new ones develop, the blood count is of great value. If it is confirmatory it may be an important indication for immediate operation; if negative, it is unreliable in so small a percentage of cases that unless there be present some other symptom pointing clearly to operation, one is usually justified in awaiting further developments.

Table of Cases.

GUNSHOT WOUNDS OF THE ABDOMEN.

By Gray G. Holladay, M. D., Portsmouth, Va.

Gunshot wounds which penetrate the abdominal cavity may, for convenience, be considered in practice as of two kinds, those received in civil life and those received in war. The treatment of these two kinds is exactly the reverse. The teaching of such men as Treves and Makins, of Great Britain, and of our own Nicholas Senn is, that gunshot wounds of the abdomen received in war do better when let alone. Borden in his Prize Essay says: "Traumatisms, which might be treated conservatively in civil practice, often require radical operations under the environment and conditions incident to military surgery; and, on the other hand, injuries, which in civil practice would require immediate surgical intervention, are frequently best treated expectantly, under the conditions which obtain in the field. The latter is well illustrated in the difference which obtains in civil and military surgical treatment of gunshot wounds of the abdomen. With the resources of the civil hospital and surrounded by aseptic safeguards, the civil surgeon uniformly opens the abdominal cavity whenever penetration is suspected. While the military surgeon, having in view the frequent recovery of such cases when treated expectantly, and knowing the almost certainty of producing infection under the conditions which obtain in the field hospitals, does not usually resort to laparotomy unless death without operation may be considered certain. Makins quotes Watson Cheyne as follows: "After the fighting at Karre Siding, on March 29th, of ten wounded (five having died within twenty-four to twenty-eight hours) nine were let alone and four died within the next twenty-four to thirty-six hours. Five were alive on April 1st and one upon whom I operated died on April 2d. (One of the others died later.)'

Senn wrote, that so far as he knew, there were but four operations done for gunshot wounds of the abdomen during the Cuban campaign. He says later, in speaking of these cases: "Four laparotomies for gunshot wounds were made here by a volunteer surgeon, but as all the patients died it was deemed expedient to assign him for duty where he could do more good than harm." This is somewhat modified when he says later: "This unfavorable experience should not deter surgeons from operating in the future in cases in which from the course of the bullet it is reasonable to assume that the bullet has made visceral injuries which would be sure to destroy life without surgical intervention." I would add to this, or where a serious hæmorrhage is taking place. Makin tells us that "perforating wounds of the small intestines are very fatal injuries; every patient in whom the condition was certainly diagnosticated died." Otis wrote that he doubted if there was even one incontestable instance of recovery from wounds of the small intestines. He gives five cases which were under observation during the civil war, and says of them: "The five foregoing cases are the only instances of recovery from gunshot wounds of the abdomen reported during the war, in which there was any plausible

ground for suspecting that the small intestine was the seat of the lesion." In that war there were 3,717 perforating wounds of the abdomen with but seventy-nine cases where the stomach was injured. In the Spanish-American war, in addition to the four cases spoken of before, there were forty cases in which there was no operation; of these forty patients, twenty-five died; a mortality of 62.5 per cent.

In civil life the experience of all surgeons is that those patients operated upon promptly frequently get well, those treated expectantly usually die. In these days when small calibre but very high power rifles are used in warfare, experience has taught that the percentage of recoveries is very much less with operation than without, except under the most favorable conditions. These are seldom or never found at the front. "To summarize, it may be concluded that modern surgical methods have not as yet proved available to markedly reduce the mortality of the wounded in penetrating wounds of the abdomen received in war, but that the mortality in these cases has been lowered to some extent by the use of the small calibre rifle." (Borden.) In civil life the reverse is true, because of the very different character of the weapon usually used and the different character and surroundings of the patient.

Personally I believe that all cases of gunshot wounds of the abdomen in civil life should be operated on at the earliest possible moment, unless there is positive evidence that the cavity has not been penetrated; for I think it far safer and better surgery to take it for granted that harm has been done than to sit still and await symptoms. When well defined symptoms of intestinal injury manifest themselves it will usually be too late for surgical intervention to be of avail.

From the location of the wound of entrance I do not believe that any one can say what deeper structures or organs have been injured, nor do I believe that any one can say whether or not its contents have been injured, even when it is known that the cavity has been penetrated. The angle at which the ball strikes the wall may cause it to take any kind of a course, and it is frequently difficult, if not impossible, to get any idea from what direction the ball came.

I recall one case (Case IV) where, judging from a previous case, I was certain that the large intestine had been injured, and laughingly remarked that had the ball entered at a similar spot on the right instead of on the left side it would probably have done an appendectomy. Upon operating I found that the large intestine had escaped injury, but that the bullet had missed the appendix by the fraction of an inch, it having traversed the abdominal cavity, perforated the mesoappendix and grazed the caput coli. Again, I believe that where the bullet enters below the umbilicus, if the intestines are empty, while the fæcal extravasation is less, the chances are better for a large number of perforations, for the empty small intestines naturally gravitate toward the pelvis, and a bullet is perhaps more apt to perforate an empty collapsed coil than one distended with gas. I believe that many times bullets will enter the abdominal cavity above the umbilicus and

do no harm, and in this opinion I but follow the oft expressed opinion of Senn, and it is derived from experiments and cases recorded by him and from my experience in my own cases and those seen with others.

In regard to symptoms I regard an increasing rigidity of the abdominal muscles as the most important single symptom of visceral injury, and in the absence of all other symptoms, but with an increasing rigidity, I should never hesitate to operate. In my experience the pulse, even in patients when there was a large hæmorrhage, has not been as rapid as I should have expected to find it. It will always be rapid enough, however, if there is a beginning peritonitis from fæcal extravasation; and it is a source of ever growing wonder to me how patients can be so dangerously injured and yet show so few symptoms of more than a trifling injury, as many of these cases do, even after a lapse of several hours. In every case I have seen where there has been a visceral injury, no matter what other signs or symptoms were absent or present, there has always been present an increasing rigidity.

Right here I may mention the hydrogen gas test, and if I may be pardoned for so saying, I "mention but to condemn it." To my mind it is far less certain and very much more dangerous than an exploratory laparotomy. Every particle of fæcal matter which escapes from a perforation adds to the gravity of the case. When this test is used who can say how much fæcal matter is (or may be) forced out by the gas? When an exploratory laparotomy is made under the proper surgical technique, even if no perforations are found, the dangers of the operation are not so great as those incurred by the gas test, should there be a perforation.

When operating I think it is the safer plan to suture each perforation as found, as I think there are several advantages in this method. Small perforations in the mesentery which are not bleeding may be let alone, especially when there is need for haste, as may wounds of the omentum. Should a large vessel in the former be cut, however, it will probably render a resection of the gut necessary, and in the latter a portion of the omentum may require ligation and removal. For suturing the liver I have found nothing so good as a very large needle ground down to a very blunt end, armed with large catgut.

I differ from those eminent authorities who tell us, as almost all of them do, that the abdomen should be opened in the median line in all cases. In this I may appear presumptuous, but I can see no good reason for this advice, and, in the light of my present experience, I shall not follow it unless there exists some very strong reason in some special case. Of course, where there are two or more wounds of entrance the question is rendered more difficult. In such a case (Case III) I should take chances and open where the most important organs were probably injured.

Also, I differ with those who contend that a probe should never be used, for, as the late Greig Smith well said, "where a bullet has passed, surely a probe may follow without much increase of danger." However, I seldom use a probe until the patient is on the operating table ready for operation, and then

I use it more as a guide than as a director. (Yet I always use a "director.") The question of resection will have to be decided in each individual case, as no set rules can be given. Where a large vessel in the mesentery is cut, or where perforations are so close together that by suturing them the lumen of the gut will be too much narrowed, or where one perforation is so large that suturing it will have the same effect, a resection will be necessary. In one case I have resected, and in another I have not, when the surgical indications were just as strong apparently in one as in the other.

Drainage, too, is another matter about which no fixed rule can, in my opinion, be laid down. "When in doubt, don't drain." When free fæcal matter is found in the cavity, or when there is a beginning peritonitis, or when for any reason it has been necessary to use irrigation, I should drain. In Case II, had I known that the patient had drunk the milk I should have drained; not knowing it I did not drain, and, as things went, I am glad that I did not know it. In cases where four or more hours have elapsed between the receipt of the injury and the operation it will be well to drain. I think that, naturally, where there is much hæmorrhage more fæcal matter may be extravasated, with less danger than where there is a less amount of blood poured out in the abdominal cavity, for where there is a very free hæmorrhage the fæcal matter is of necessity "diluted," and, therefore, less virulent.

As regards mortality, in one series of 110 operations there were thirty-six recoveries, a mortality of 68 per cent.; in another series of ninety-six cases seventy-one patients died, a mortality of 73.95 per cent. To-day the mortality seems to vary between 52 and 73 per cent. Fenner has reported six operations with one death, and Douglas had eight operations with two deaths. I have operated five times, and four of the patients made perfect recoveries and the fifth died of double pneumonia after all the perforations had healed.

The results of operation depend very largely upon the length of time which elapses between the receipt of the injury and the operation. Those patients who are operated upon within four hours show about 20 per cent. less mortality than those operated upon after a longer time.

As regards the number of perforations, in a series of eighty-one cases there were found 439 perforations, an average for a case of 5.4. In a very much larger number the average has been between five and seven for a case. Iden rports one case where there were nineteen perforations. In 165 cases, there were but nine in which all the perforations were not found.

In the five cases which I now report the average number of perforations of each case was 9.4 of the gastrointestinal tract, one ball passed also through the liver and the diaphragm. The average time which elapsed between the shooting and the operation was 8.8 hours.

CASE I.—J. M.; age thirty seven years. This man was shot at 11 p m., 158 miles from my home, and was brought to me, coming part of the way on a freight train. After being shot he had done some walking about. It

operated upon him at 7 p. m. the next day, and at the time of the operation his condition was surprisingly good, although he failed very rapidly after the operation was As so often happens when an abdominal cavity full of blood is opened, I presume that it is from the relief from pressure which invites collapse similar to that

sometimes seen in tapping for ascites The wound of entrance was three inches to the left and on a level with the umbilicus, and the ball (a. 32 calibre pistol ball) was cut from under the skin just above the left trochanter major. The abdomen was opened through the bullet hole and the omentum prolapsed into the wound, thus preventing any hæmorrhage from appearing exter-nally. As soon as this omentum was replaced there was a very free gush of blood. (One objection to opening through the bullet hole; the escaping blood may greatly obscure the field.) Upon getting into the cavity it was found to be full of blood with much fecal matter floating about. Two perforations and a slit one and one half inches long were found in the descending colon. A further inches long were found in the descending colon. A further search revealed six perforations in the small intestine within a space of not over four inches. These were so close together that a resection was deemed best and hurriedly done, and, as the patient's condition was now very bad, a Murphy button was used. Besides these perforations there were several in the mesentery and omentum (six or eight), but as I am not now sure of the number, I put this case down as having nine perforations. Gauze drains were used in this case, and the patient made a good recovery, though not a very rapid one. His bowels moved naturally on the third day. At the next movement he passed a very large number of watermelon seeds; his last meal before the shooting had been made of watermelon. This case was published in the International Journal of Surgery for April, 1907

Case II.—E. K.; age fifteen years.

This boy was shot about 5 (?) p. m. with a .22 calibre pistol, and walked to the hospital, where a fly dressing was put on over the wound; then he walked home and for supper drank a glass of milk. I operated upon him at 10 p. m., and opened him up through the bullet hole, which was two inches to the right and slightly above the umbilicus; some blood was found in the cavity, but no perforations could be found in the intestines. The stomach, which was in view, seemingly rather low, was next examined, and a perforation was found in its anterior and one in its posterior wall. There had been some leakage of stomach contents, which was carefully sponged out. The perforations were sutured and the abdomen cleansed without drainage. The boy made a rapid and uneventful recovery.

CASE III.—T. H.; age twenty years

This man was shot between 5 and 6 o'clock in the after noon with a .32 calibre pistol, while stealing chickens. He was carried some miles to the county jail, and later brought to the hospital, where I saw him at 11:30 p. m. His condition when I saw him was very bad, but in spite of the shock I decided to operate at once. He had been shot twice, one ball entering between the seventh and eighth ribs, the other about two and one half inches to the right of (or behind) the anterior superior spine and on a level with it. In this case, as there were two wounds of entrance and very marked rigidity of the abdominal wall. I decided to open the abdomen through the median line between the ensiform cartilage and the umbilicus. There was some blood in the cavity, and solid fæcal matter was protruding from the perforation in the transverse colon. This was at once cleaned off, and the perforation sutured. Another perforation was found in the transverse and two in the ascending colon; these were at once sutured. The ball was found to have passed through the liver and diaphragm. The wound in the liver was sutured with large phragm. The wound in the liver was survived acteut. The appendix, which came into view, was acutely categories and a freed concretion, was reinflamed and, as it contained a fæcal concretion, was re moved. The second ball had not entered the abdominal eavity at all and was, a few days later, cut from under the skin of the right buttock. This case was closed without drainage, and the patient made a quick and uneventful

CASE IV .- G. D.; age fourteen years.

This boy was shot between 3 and 4 p. m. with an un-known weapon and from an unknown direction. I saw him between 2 and 3 a. m., when his condition was only

fairly good. I found the wound of entrance to be three inches to the left and slightly below the umbilicus. I at once opened him up through the wound. The cavity was full of blood with omentum acting as a plug, so that no blood was escaping externally. Twenty-one perforations were found in the small intestines and sutured as found. From many of these fæcal matter was oozing. Four perforations of the mesentery were found, and, as two of these were very large and ragged, they were sutured. A large vessel in the mesentery had been cut, and it was from this that most of the blood was coming. The ball had gone across the abdomen from left to right, gone through the mesoappendix and grazed the caput coli. Gauze drains were used and, at the first dressing, during the boy's violent struggles, a stitch pulled out and a large amount of the small intestine protruded. In spite of the number and character of the perforations the boy made a splendid recovery and was well in three weeks. In this case the perforations made a most interesting study, for there were all kinds, some very small and clean cut, as if done with a punch, some very ragged, some as large as the end of my thumb, some had the mucous membrane protruding and some did not. In several places there was profituding and some did not. In several places there was one perforation in the gut and not another one nearer than twelve inches; in other places there were three perforations within two inches. Evidently, in some parts of the canal, the ball had traveled inside the lumen. Otts says that "the mucous membrane prolapsed almost constantly." This has, however, not been my experience by any means.

CASE V .-- T. R.; age thirty-seven years.

This man was shot twice with a .32 calibre pistol at 7 p. m. One ball entered the abdomen three and one half inches to the left and on a level with the umbilicus and passed right through, being cut from under the skin of back at a little higher level. The other ball entered his left thigh. The muzzle of the pistol was pressed right against the man when the first shot was fired, and his clothing was set on fire. I operated upon him at 9:30 p. m., and compand him through the bullet held. I found much and opened him through the bullet hole. I found much blood in the cavity, with some free fæcal matter. Seven perforations were found in the small intestine; of these three were sutured, and twelve inches of gut resected, because to close the four perforations entirely would have closed the lumen of the gut. Gauze drains were put in and the abdomen closed. The next morning the man complained of difficulty in and of great pain on breathing, and stated that he could not breathe with any comfort except when lying on his side. His bowels moved on the second day and again on the third. He was dressed daily, and while there was some discharge it was of normal odor and appearance. Except for the lung complication, which was diagnosticated as pneumonia, he seemed to be doing nicely. He died quite suddenly in collapse at the end of eightyfour hours.

The autopsy showed all the perforations healed entirely and the line of anastomosis good. There had been no leakage, and while there was a mild grade of peritonitis present it was not thought to have accounted for his death even if no other cause had been found. The lower lobe of the left lung was solidified, as was the lower part of the right lower lobe. The patient had been frequently turned on his sides. There was also no pus in the abdominal

Note.—Since the foregoing was written I have operated in two more cases, with recovery in each. In one the colon was perforated; in the other the stomach and small intestine, and in the same case an intussusception of the small intestine was found.

SOME TYPES OF PNEUMONIA ASSOCIATED WITH INFLAMMATION OF ADENOID GROWTHS.

BY EDWARD JOHN BERO, M. D., New York.

Adenoid vegetations interfere with proper nasal These vegetations are found microrespiration. scopically to be swarming with microorganisms. As a result of the air not being moistened and warmed by the passage through the nasal chambers, mouth breathers are predisposed to inflammation of the respiratory tract.

During the past year I have been impressed by certain types of pneumonia coincident with inflammation of adenoid growths. Observations made in similar cases during previous years seem to correspond to those made recently. The chief characteristics were very high temperatures, at first remittent, towards the end of the illness becoming intermit-

Pneumonia with inflammation of adenoid growths has been met in the following forms: I, Without purulent middle ear inflammation; 2, with purulent middle ear inflammation, a, the middle ear inflammation appearing early in disease, and, b, later in disease.

Group I. CASE I. -G. B., twenty-one months old; had several attacks of otitis media due to adenoid growths.

Present history: A few days before the appearance of high temperature, the child looked tired, catarrhal, slept with open mouth, snoring loudly. On the morning of November 30, 1907, temperature began to rise. In the evening the child looked quite ill. The next morning the temperature became normal, but general condition did not improve. The child breathed rapidly and coughed frequently. After a few hours the temperature rose to 106° F. Physical examination of the chest revealed the presence of râles. No consolidation was found. An otologist called in consultation found both ear drums characteristic of adenoids; suspecting a middle ear inflammation behind the more inflamed ear drum, he performed a paracentesis. No discharge followed. During the first week of December the child con-tinued to be ill. Temperature was remittent for a few days, with high exacerbations, then became intermittent. Breathing became more labored. Cough was loose. Over the upper part of the left lung, posteriorly, an area of diminished resonance with moist râles was found. This case was diagnosticated as pneumonia. From the eighth until the thirteenth day the temperature was intermittent, being every day normal or subnormal for a few hours. Inflammation of the adenoids subsided, and no purulent dis-

Case III.—(Notes.) Child, L, eighteen months old, started its illness with severe gastrointestinal symptoms and high temperature on May 4, 1908. The following day vomiting and diarrhoxa subsided, but the temperature rose to 106° F. The nose was discharging freely. Inflamed adenoids were present. Ear drums were congested, but no bulging noticed. The child's breathing became labored from nasal obstruction. Cough was loose. Over both lungs railes were present. Patches of diminished resonance and bronchovesicular breathing found over both lungs. The temperature in this case during the first week of illness was remittent; evening temperature about 106° F. From the tenth to the sixteenth day of illness temperature was intermittent. The child became well on sixteenth day. No purulent otitis media followed.

Case III.—Child, A. C., three years old. First call made on July 10, 1905, after appearance of high temperature. Examination revealed presence of inflamed adenoid growths. Diffused râles were found over both lungs. The temperature was intermittent in character and continued so for some time. No consolidation of the lungs could be detected. Being unable to find any positive signs of pneu-monia, I decided to have the ears examined. A specialist found the left ear drum very much inflamed. Paracentesis was made; no discharge followed. Course of fever had not

changed in the mean time. Spleen was not enlarged. Plasmodia were not found in the blood. Child became well after eleven days of illness. I diagnosticated the case as adenoiditis and pneumococcæmia. Adenoiditis alone could be excluded, as inflammation of adenoid growths without middle ear inflammations never give tem-

peratures for a considerable length of time.

Group II, a. CASE IV.—Annie G., three years old. History of mouth breathing and earache. On the 10th of August, 1906, child became ill, with high temperature. Temperature was remittent for first few days. Breathing labored. Numerous rhonchi, sibilant and sonorous breathing over both lungs found. On the third day of illness both ears were examined. Left drum was bulging. Paracentesis made, purulent discharge followed. Child continued to be ill, notwithstanding the perfect drainage from the ear. Diagnosis of bronchopneumonia with otitis media was made. Towards the end of the illness temperature became intermittent and continued so for five days, giving the impression of a pneumonia with four pseudocrises. The spleen was somewhat enlarged towards the end of illness, but no malarial plasmodia were found. Quinine did not modify the character of fever. Child became well on the four-

CASE V .- The child of Case I became ill again two months after previous illness. After some exposure the thild showed symptoms of inflamed adenoid growths. On the 15th of March it became quite ill. A few days later a distinct area of lobar pneumonia of left inferior lobe could be made out. Temperature at the time was remittent. Highest temperature recorded was 106.5° F. On the sixth day of illness the temperature became normal for some time after profuse sweating. Two days later a complication of measles set in. The area of consolidation remained the same. A purulent of till media followed. The eruption gradually subsided. The temperature became intermittent and continued so for over a week. On the twenty-first day of illness the layers became the results.

of illness the lungs began to resolve.

The complication of purulent otitis media observed in the last named group of pneumonia cases often hampers the observer, as it may, by itself, give the same characteristic temperatures. Bearing in mind that inflamed adenoid growths are always accompanied by a congestion of ear drums, methods must be used to prove that there is no purulent secretion behind them. To make the above supposition of the direct relation between inflammation of adenoid growths and pneumonia following it, probable, the characteristic course of pneumonia must be observed in cases without any complicating otitis

Basing the description of the adenoid pneumonia upon cases used as illustration of types, and upon others of a similar nature, I can give the following general description of adenoid pneumonia:

Child or infant previous to its illness is a mouth breather, snoring in sleep; sleeps with eyes half closed, suffers from night terrors, or has frequent attacks of otitis media. The pneumonia is preceded by catarrhal symptoms, as running from the nose, suffused eyelids, or in infants by gastrointestinal symptoms. A high temperature appears, which may become normal after a few hours, then rises again and remains remittent for some time. Child begins to look very sick. The temperature may go up to 106° F. during the first few days of illness, then subsides somewhat. The patient moans in sleep. His breathing is labored. Respiration may be between 60 to 80 to the minute. Pulse, 135 to 160. Extremities are cold. There may be frequent, dry or soft, cough. Physical examination of chest may show signs of typical lobar pneumonia or area of diminished resonance with moist râles and bronchovesicular breathing. An otologist called in consultation may not find sufficient cause for puncturing the ear drums. Paracentesis would not

show in many cases the presence of a purulent secretion behind the congested ear drum. At the end of the first week or beginning of the second, the temperature becomes intermittent. The duration of fever is indefinite. It may end in the second week or follow a protracted course in cases where a purulent discharge from the middle ear follows.

The cases described here have shown the follow-

ing characteristics:

1. Very high temperature was noticed.

2. The height of temperature did not correspond to the severity of illness, as in other forms of pneumonia, and did not make the progress unfavorable.

3. The temperature towards the end became intermittent, giving the impression of a number of

pseudocrises.

4. The same characteristic temperature was observed in cases complicated by otitis media as in those without it.

5. Complications with the exception of otitis media have not been seen in robust as well as weak

persons. 6. Early puncture of the ear drum did not modify

the course of the disease.

- 7. Spleen was not enlarged; malarial plasmodia were not found. Quinine did not modify the intermittent temperature.
 - 8. The disease had often a protracted course.
- 9. The patient was left prone to relapses of similar character in cases where adenoid growths were not removed.

Our Beaders' Discussions.

A SERIES OF PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

LXXVIII.—How do you treat acute corysa? (Closed

EAAVIII.—How do you treat sick headache? (Answers LXXIX.—How do you treat sick headache? (Answers due not later than October 15, 1908.)

LXXX.—How do you treat asphyxia neonatorum? (Answers due not later than November 16, 1908.)

swers due not later than November 10, 1908.)
Whoever answers one of these questions in the manner most satisfactory to the editors and their advisers will receive a prize of \$25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short; if practicable, no one answer to contain more than six hundred words

All persons will be entitled to compete for the prize, whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish.

address, both of which we must be at tiberty to publish.
All papers contributed become the property of the JOURNAL.
OUR READERS ARE ASKED TO SUGGEST TOPICS FOR DISCUSSION.
The prize of \$25 for the best essay submitted in answer to question LXXVII has been awarded to Dr. Maxwell S.
Simpson, of Titusville, N. J., whose article appears below.

PRIZE QUESTION LXXVII.

THE TREATMENT OF VARICOSE ULCER.

By MAXWELL S. SIMPSON, M. D., Titusville, N. J.

The typical varicose ulcer exhibits an unhealthy floor covered with exuberant flabby granulations, spots of necrosed tissue, and is surrounded by an

infiltrated zone supporting an eczematous skin (the dermatitis hæmostatica" of Klotz and which he regards as distinct from true eczema) of varying intensity. The venous circulation is always faulty; if the varicose veins do not stand out above the level of the skin they are imbedded in a sodden tissue which does not pit on pressure, is glazed and tense on the surface, differing thus from ordinary cedema in which mechanical obstruction only is offered to the return of the blood ("solid cedema"-Lister).

It is commonly situated on the front of the lower third of the leg, or over the malleoli, where there is but little celluloadipose tissue. It heals but slowly, and the ineffectual effort of the surrounding skin to form a cicatrix bounds the wound with a hardened bluish red border, preventing further epidermization.

Innumerable remedies and methods of treatment, each successful in a certain number of cases, spring up in so intractable a disease as this, and it is well before advocating any one plan to give them some consideration. In the early eighties oily dressings were much in use, chiefly oiled gauze with several layers of dry gauze and a protective layer of rubber tissue. Sometimes balsam of Peru was added to the oil; one of the best mixtures being balsam of Peru, alcohol, and castor oil; and sometimes iodoform was added. The castor oil mixture is viscid and will remain on the wound without spreading. If sufficient absorbent material is used the wound will remain moistened yet drain its serum, and the granulating surface remain clean and dry when the dressing is removed, but this dressing is no protection against erysipelatous infection, does not actively prevent suppuration, and the time required for healing is prolonged.

The aqueous dressings of Lister were then used; sterile gauze, medicated, and with an impermeable covering. With the moist dressings there is no retention of secretions, depletion ensues and more rapid repair results. But it is far from satisfactory. By keeping the surface warm and moist the dressings act as poultices, increase inordinately the secretions from the wound, the granulations become exuberant, and the eczematous condition of the skin is increased. Acute cedema with exfoliation of the epidermis is of common occurrence. Proliferation of bacteria render the dressings putrid, and frequent

change becomes necessary.

A routine plan of treatment will not suffice; success must be based on causal factors. In many cases constitutional attention is not called for, but internal medication should not be overlooked. Many slow healing ulcers improve through influence of the iodides even when not syphilitic. The active elements in this form of ulcer are varices and eczema, and no plan of treatment is successful that ignores them. Pressure applied smoothly and uniformly is essential. This has been so long recognized that Ibn Sina Avicenna, the Arabian physician and writer of the tenth century, favorably indorsed it. Thomas Baynton in 1792 treated these ulcers by adhesive strips so arranged as to approximate the edges of the wound and used a roller bandage for pressure. Martin, of Boston, introduced the use of the rubber bandage for the same purpose, and to-day all these expedients, or the principle involved, are in use.

During a term of service of nearly two years among the native tribes of Luzon, P. I., a region peculiar even among other tropical countries for its vast number of skin diseases, and not least varicose ulcers, the writer made use of a method which at the present time he desires to recommend as the treatment par excellence for this affliction, and is

the following: If the patient can be kept in bed, hot fomentations or emolient poultices are first applied and the limb elevated. If the patient cannot have the benefit of this procedure, as a substitute it may be packed overnight with lint saturated with petrolatum, or an oily dressing applied. After twenty-four hours of this treatment the floor of the ulcer is cleansed of all crusts of inspicated secretion, epidermis, and necrosed tissue by placing the limb in a hot water bath and gently rubbing with mops of absorbent cotton and gauze. This may be aided by a three per cent. solution of hydrogen peroxide, particularly in ulcers of an atonic base; or, it may be mopped with a solution of potassium permanganate (4 in 1000), or of bichloride of mercury (1 in 1000), especially if fœtid. The redundant granulations and marginal induration are thoroughly removed by curette and curved scissors. A second application of the oiled dressing is then made, to which some stimulation is added to overcome the tendency to necrosis of the granulations. This may be iodoform, lightly dusted over the surface, or aristol in a ten per cent. ointment; the latter is odorless and has an excellent effect on the eczematous zone, or bismuth subgallate, or ichthyol. On removing this second dressing the wound should show smooth margins, with a base of healthy granulation. It seldom has to be repeated for that effect.

Having thus secured a simple healing ulcer, the surrounding indurated tissues, the eczematous skin, and the varices must receive attention and a more perfect circulation be established. It is necessary now to keep the wound as dry as circumstances will permit. Moisture propagates eczema, plain water irritates, unguents and oily dressings retain the secretions, are a nidus for microorganisms, induce phlegmonous infiltration, and have a tendency to necrosis of the granulations. A dry dressing favors epithelial growth, insures drainage without irritation, checks proliferation of bacteria, and the formation of epithelium over granulating surfaces pro-

ceeds more quickly and easily. This is best accomplished by means of a finely levigated powder. It may have as its base talcum (magnesium silicate), impalpable and nonirritable, or zinc stearate. To this may be added acetanilide, which is desiccant and hæmostatic but not germicidal. Acetphenetidin, now inexpensive, is more analgesic. In an extensive use of acetanilide in this manner by the writer toxic symptoms have never been encountered. Its action is to somewhat retard the growth of granulations, but which may be stimulated when necessary by the addition of iodoform or aristol, which may be first dusted over the surface. Then a mixture of one third acetanilide or acetphenetidin with the base, in a generous layer, is placed over the ulcer. A pad of six or more layers of sterile gauze then covers the wound, and a

roller including the foot and extending to or above the knee joint is laid snugly, with a uniform pressure greater near the ankle than above. It should be applied while the foot is elevated to drain blood from the distended varices, aided by gentle massage.

The first dressing is not to be removed for three days. With dressing forceps and absorbent cotton cleanse the wound, maintaining its dry condition, but removing necrosed tissue and purulent secretion. Make a liberal use of the powder and reapply gauze and roller. This treatment rapidly develops healthy granulation and heals kindly with most gratifying results.

When cicatrization is completed an elastic stocking must be worn. This must be made to measure, properly fitted, and have an equal pressure, and extend from the instep to above the knee. It should not be worn next to the skin, but over a thin stocking, and when removed at night the leg must be bathed in cold water and treated to friction with a woolen cloth.

The preference for this treatment is obvious. The time of healing is much shortened, pain is lessened, the dressings are fewer, cicatrization is firmer, and the result permanent.

Dr. Edward Adams, of New York, says:

There are three essential indications to be fulfilled in order to treat a varicose ulcer with success:

- I. To provide for the absorption and disinfection of the discharges.
- 2. To improve and restore the circulation to its normal condition.
- 3. To treat the varicose veins by palliative or radical means.
- 1. Cleanliness is best obtained by washing the leg once a day with soap and hot water, shaving when necessary. Warm applications should be used, such as saturated solution of boric acid, two per cent. solution of aluminum acetate, bichloride of mercury, I to 8000; and where there is a profuse foul discharge, two per cent. solution of creolin can be employed. The stronger antiseptics are uncalled for and often give rise to eczema. The dressing should be removed every other day at first and the skin about the ulcer should be cleansed each time, the fat being removed by ether. Wet dressings are to be preferred becaues: 1, They are aseptic; 2, they permit free drainage; and 3, no new granulations are disturbed in changing the dressing. Under such treatment, in most instances, the swelling and irritation will subside and the ulcer becomes cleaner and granulating in appearance, especially if the patient is confined to bed with elevation of the limb, not only until cicatrization is complete, but also until it becomes firmly organized. This often means overcoming the objections of the patient, who is only too much inclined to stand or sit up for a few hours as soon as the condition improves and the pain ceases, or who is unable for social reasons to give the limb the necessary rest and protection. Ambulatory treatment is successful at times, but recovery is more rapid by the recumbent position. In cases where the skin will not tolerate moisture, or where the ulcer is small with very little discharge, various dusting powders may be used, such as iodoform,

dermatol, calomel, aristol, boric acid, and orthoform, either alone or in combination with starch powder. Where the ulcers are sluggish, in order to stimulate the granulations a silver nitrate stick can be used with beneficial results. Tincture of iodin, balsam of Peru, or a five per cent. solution of zinc chlorid, give at times good results. A twenty per cent. solution of boric acid petrolatum, a ten per cent. ichthyol ointment, or the red oxide of mercury, can also be used.

2. To improve the circulation. Whenever possible the patient should be kept in the recumbent position with the limb elevated, but when circumstances do not permit of such, the veins can be supported in various ways. Elastic stockings are excellent, but expensive and not durable. Bandages of rubber cloth or woven bandages rendered elastic by the character of the mesh, or Martin's plain rubber bandage, may be employed. The latter is put on smoothly but not tightly, for in walking the leg swells, so that a uniform pressure is established. As the rubber prevents evaporation, it acts like a wet compress stimulating the granulations, but often producing eczema around the ulcer. The bandage should be washed carefully at night with soap and cold water, and must be kept clean. In one patient a firm elastic stocking of vulcanized rubber will give the greatest ease and comfort, while in another the irritation caused by such a bandage will prove unsupportable. The cotton web bandage in such cases is a good substitute and is found very serviceable. The essential feature of ambulatory treatment is a good bandage to prevent congestion, and, to my mind, Unna's bandage is the ideal one. The paste necessary for the bandage is prepared as follows: First dissolve four parts of the best gelatin in ten parts of water by means of a hot water bath. While the fluid is hot add ten parts of glycerin and four parts of powdered white oxide of zinc; stir energetically until the mixture is cold. Always melt the paste before using by placing the receptacle in a hot water bath, as it must be applied while hot, solidifying on cooling and resembling rubber. The limb should be carefully cleansed with soap and water, then alcohol, and must be thoroughly dried before the paste can be used. After heating, it is brushed on from knee to foot and a gauze bandage is applied, cutting it frequently instead of reversing, in order to prevent wrinkles; then another layer of paste and another layer of bandage, until a support of several thicknesses is obtained. If the ulcer is secreting freely, a window can be provided or the dressing changed. After the last application of the paste some nonabsorbent cotton can be applied, giving the bandage a mole skin finish; or some talcum powder can be used, giving the appearance of a plaster of Paris dressing. The bandage can be worn anywhere from two to eight weeks.

3. Palliative and radical means. Another method of treating these ulcers is by means of strips of adhesive plaster, an inch in width, applied shinglewise, directly over the ulcer and reaching some distance above and below it. Curetting the ulcer, x ray treatment, or skin grafting may be resorted to in healing this condition; and of the latter, Thiersch's, Krause's, or Reverdin's method can be employed.

The radical method of treating varicose ulcers after healing, especially when caused by enlarged veins, is by operative interference. The operations chiefly performed are those of Trendelenburg, Schede, or Mayo. Trendelenburg's operation is the ligation and extirpation of the internal saphenous vein by a longitudinal or transverse incision at the upper and middle thirds of the thigh, about one and one half inches in length, along the course of the vein. In suitable cases the relief follows quickly, the wound healing by primary union in about ten days. The operation, however, is not without its dangers, for, in spite of complete asepsis, thrombosis of the proximal stump and embolism have occurred, giving a warning against operating without a strict indication.

Schede's operation consists of a circular incision at the upper and middle third of the leg, encircling the limb, and removing all the veins to the deep fasia.

Mayo's operation is by the subcutaneous method of dissection. He exposes the vein high up, divides it, and passes over the lower portion an instrument which resembles a dull wire curette. This can be wormed along beneath the skin, dissecting out the vein until it breaks, usually three to four inches from the first exposure. The instrument is reintroduced and the procedure followed as above.

After an operation for varicose veins, the leg should be placed in a Volkmann splint and the patient should remain in bed for three weeks. Massage with active and passive motion should be gradual, and no active work should be attempted until three weeks more have elapsed. A supporting bandage should also be worn at least for six months after an operation of this character.

The chief complication occurring with varicose ulcers is phlebitis. Rest, with elevation of the limb and a wet dressing, must be insisted upon; however, if the case is seen early enough, an operation can be performed with excision of the thrombus.

Constitutional treatment should be given when necessary, and tonics, like iron, strychnine, and arsenic, are advisable. Constipation and other ætiological factors should be treated accordingly.

Dr. Frederic H. Wilson, of New York, remarks:

The varicose ulcer. What a series of pictures is conjured to the brain of the clinician by the mere mention of that name. To those of us who have spent hours in a dispensary room (and who of us has not), the memory comes of an endless line of stout "cook ladies," buxom mothers of from eight to ten children, and beery, red faced motormen, each presenting a mammoth calf of rainbow hue, bearing its erosion and wrapped up in its dirt begrimed bandage. How they sit on the bench outside the door and proudly compare notes on how many years they have been coming to the clinic for this same ulcer, and what tides of students and nurses have ebbed and flowed past them, learning to put on leg bandages and, incidentally, to be sure, treating (?) the ulcer at the same time. As one of the veterans put it, "Sure, I don't know phwat they'd hov done in this horsepittle without my leg for the students to practise on, these seven years.

And right there, in that seriocomic remark, is a caustic commentary on the average treatment of varicose ulcer. Do we not too frequently regard it more as a nuisance than a disease, and pass it by with the application of a little ointment and a careless bandage? And yet I think that, taken seriously, it forms as interesting and instructive a feature of our clinic work as any other one condition we meet. Far from being something to be handed over to the nurse or student, on the contrary it often becomes a "foeman worthy of our steel," and many are the clinicians who have felt themselves baffled by its obstinacy. Select the worst one in your dispensary, gentlemen of the clinics, and make up your mind that you are going to conquer it, and then see if you have not found a hard

proposition.

How are we going to begin? In the first place, on true surgical principles, and treat it aseptically. Use sterile instruments and dressings, touch it with clean hands, and impress on the patient the importance of guarding it from dirt, and you will have gone a long way toward the desired result. The varicose ulcer, by its nature and its location, collects unto itself large quantities of dirt, and the abolishment of this is of first importance. Then, having got it clean and kept it so, begin its cure. I believe in that "elixir of life," hydrogen peroxide, for a first application. Flood the ulcer with that and do away with the ichthyol, the boric acid ointment, and the oil. Gently dry off the peroxide and prepare some narrow strips of sterile adhesive plaster. Apply these crosswise right across the ulcer, even though they do not seem to be doing any good in the way of bringing the edges together. Put on some fluffed gauze and apply a bandage from toes to knee. When you dress it next time, you will find that the edges under the plaster have become a little turned in and drawn toward each other, and that is another big step toward cure. You will find a more or less abundant secretion, yellow, foul, and noxious. This is not a sign of wrong treatment; on the contrary, it is the natural result of the strapping. Again flood the ulcer with peroxide, but do not remove the straps unless they are very loose. Then apply a very small amount of balsam of Peru and castor oil, equal parts, cover with sterile gauze, and rebandage. Use the balsam not oftener than once a week, in the meantime keeping up the peroxide washing and adhesive dressings. The strapping will gradually make its effect noticeable, and the ulcerated area will become smaller. Do not expect very rapid improvement. The condition has probably been present for years, everything is against its restitution to the normal, and the progress of repair will be painfully slow. But keep at it and the result will justify the trouble. I do not mean to say that the treatment just outlined will cure every case of varicose ulcer you meet, but I do believe it to be the sanest and most valuable method we can use, and certainly a reason can be given for every part of it, which is more than can be said for the ointments and oils so indiscriminately applied in most dispensaries.

A word as to that most important adjunct, the bandage. It should be of muslin, of course, and pref-

erably about three inches wide. The large calves to which they are applied offer strong inducements to put on the beautiful "picture bandages" of the textbooks, with their spiral reverses, etc. But the patient is fortunate indeed if this kind of bandage holds until home is reached, when it must be put on again, this time usually in a way that makes the leg resemble a bundle tied up with cord. Beauty should be a very secondary consideration here. The object of the bandage is to hold the dressing in place, and especially to afford firm, even pressure, not too tight, on the veins of the leg until the next time the ulcer is dressed. And if it loosens or comes off in that time the whole treatment is worthless, and that much time is lost. I have found the so called "bellevue walking bandage" to be the most reliable for these cases. It certainly is not a thing of beauty, but it is a joy forever to the doctor and the patient, and that is what counts. I anchor it at the ankle, then go down to the toes and work back to the ankle. From there it is taken with one large spiral all the way up to the knee and the calf, then covered in with figure of eight turns. The bandage is finished with simple circular turns around the leg above the calf and fastened with a strip of adhesive plaster. Never pin it and especially never split and tie it, for obvious reasons. I have repeatedly seen this bandage keep its position for a week, the patient going about her work as usual.

In conclusion, I want to advocate strongly the need for establishing, in our large city hospitals, wards for the treatment solely of these cases. There are thousands of men and women pursuing their work in our cities, suffering the while from this chronic condition, which is so difficult of cure unless they are confined to bed, and yet scarcely a hospital will admit them, because of the triviality of their ailment. Could they receive hospital care and nursing for a short time the results would be plainly evident, and, moreover, time and space now taken by them in the dispensaries could be saved for the treatment of more serious cases, at present slighted,

of necessity.

(To be continued.)

LETTER FROM LONDON.

The Sixth Report of the Cancer Research Fund.—Treatment in the Cancer Hospital.—The Care of Mental Defectives.—A Case of Alleged Malpractice.—The Franco-British Exhibition.—An Audacious Advertisement.

LONDON, August 25, 1008.

The Sixth Annual Report of the Imperial Cancer Research Fund has just been published, and contains much interesting matter. During the year there has been a very great increase in the scope and number of investigations conducted in the laboratories, and these have been made possible only by the largely increased accommodations liberally placed at the disposal of the fund by the Committee of Management of the Royal College of Physicians of London and the Royal College of Surgeons of England. The laboratories have also been visit-

ed by a large number of distinguished scientific men from America, France, Germany, and other coun-Dr. Edgar Gierke, assistant to Professor Aschoff, of the University of Freiburg, worked in the laboratories for six months, and since his return to Germany he has been appointed director of the Pathological Institute at Carlsruhe, and a paper by him, founded on his work in the Imperial Cancer Research Fund laboratories, will appear in the scientific reports of the fund. Dr. Murray deals with spontaneous cancer in mice, on which subject he has been occupied four years. He has also been working with a transplantable squamous celled carcinoma. At the time of the second scientific report the value of Jensen's tumor was not generally recognized, and not a few even disputed its cancerous nature. Now, the investigators working under the Imperial Cancer Research Fund have obtained a large number of inoculable tumors, and all have admitted the really cancerous nature of the growths. The value of trypsin as an empirical remedy in cancer has been investigated, but it was found that the benefits alleged for the treatment by this ferment had not been confirmed. It has been suggested that an international committee on cancer research should be established, with its headquarters in Berlin, and the general superintendent, Dr. E. F. Bashford, has been invited to join it, but the Executive Committee of the Imperial Cancer Research Fund considers that more advantage is to be gained by encouraging an active interchange of views and of material between the workers in the laboratories in the various countries.

Investigations on cancer are also being made from the clinical standpoint in a special department of the Middlesex Hospital and in the Cancer Hospital. At the latter institution there are 110 beds available for the treatment of cancer cases. A notable feature at this hospital is that any remedy brought forward as a cure for cancer is impartially investigated and fully tested. Among the methods which have been tried lately are the trypsin and amylopsin treatment, the treatment by Colev's fluid, that by Doyen's serum, the various forms of electrical treatment, x rays, high frequency currents, and also the treatment by violet rays. tunately, none of these methods have fulfilled the expectations of those who introduced them, although some of them have their special uses in alleviating the various forms of cancer. Dr. Paine, who is in charge of the pathological laboratory at the Cancer Hospital, considers that all cancer research should be conducted in close conjunction with the observation of patients, and for this reason he thinks that this institution offers many advantages as a centre of cancer research, seeing that its wards always contain upwards of a hundred cases of cancer and allied diseases.

The Royal Commission which was appointed in 1904 to consider the question of the care and control of the feeble minded has just issued its report. The commission held its sittings in London, Edinburgh, and Dublin, five of the members visited the United States, and various members from time to time visited institutions in Great Britain and on the Continent. In all, 248 witnesses were examined. From all these sources the commission has amassed

and considered an enormous bulk of information, which will be published in eight large volumes. Only the last of these, containing the whole conclusions and recommendations of the commissioners, has been issued. The report points out the very grave state of affairs at present existing. The problem of the mentally deficient has not met with the attention it deserves, and as a result of their inquiries the commissioners recommend some far reaching alterations. One section of the report deals with criminal lunatics and is in strong support of Lombroso's doctrines. The commissioners found that large numbers of persons were annually committed to prisons for repeated offenses, which, being the manifestations of a permanent defect of the mind, there is no hope of repressing, much less stopping, by short punitive sentences; consequently they make the recommendation that all courts of justice, including courts of summary jurisdiction, should have the power to order the detention of a convicted mentally defective person in a suitable institution, instead of pronouncing a sentence of imprisonment, and they should be detained there until the approval of the Secretary of State for their discharge has been obtained. Another important section deals with mental defect and inebriety.

The commissioners found that from sixty to seventy per cent, of the habitual inebriates dealt with under the acts were mentally defective. In harmony with this view, they arrived at the conclusion that mentally defective inebriates should be dealt with in the same way as other mentally defective persons, and that all processes for the detention of the insane should also apply to the mentally defective inebriates. The whole document is of extreme interest and importance, and if the recommendations of the commissioners were adopted, it is not too much to say that there would be a vast improvement on the present system. In this connection it is very interesting to note that in 1891 there was established in Belgium a system of periodical inspection of prisons by alienists, giving recognition to the view held by the principal alienists and criminologists that a large proportion of the persons undergoing legal detention were insane. Many distinguished psychologists in Great Britain are enthusiastic advocates of the Belgian system and recommend its introduction into this country.

An interesting case of alleged malpractice was tried at Greenock, in Scotland, recently. woman on whose behalf the action was brought was a primipara, and it was alleged that the medical attendant had failed to take the usual and proper antiseptic precautions at the birth. The doctor claimed £25 for professional attendance, and the defendant put in a counter claim for £89, being fees and expenses incurred owing to the negligence of the plaintiff. The sheriff pointed out that the implied condition of the contract between a medical man and a patient was the exercise of average skill, although it was not always easy to determine the standard of such skill. Summarizing the charge of negligence, it amounted to this, namely, that the forceps, needle, sutures, and scissors used at the confinement were not sterilized, that the birth was unduly hurried by the use of the forceps, that the cervix was badly torn and the perinæum severely

lacerated, and that the medical man neglected his patient by leaving her to go on a holiday when she was in a critical condition. With regard to sterilization, the sheriff found it was not usual to effect this by boiling in a private house. With regard to the use of the forceps, that did not, in his opinion, constitute gross negligence. There was no medical evidence as to the tear in the cervix, while the rent in the perinæum had nothing to do with the patient's condition, for it healed up aseptically. As to the cause of the illness, he was quite unable to hold the view that it was due to unsterilized instruments. The claim for fees was allowed with costs, and the counterclaim dismissed. This case is of interest as disclosing to the general practitioner certain professional risks to which he is exposed.

The London Hospital has a very interesting exhibit at the Franco-British Exhibition, one of the notable features being a varied assortment of dainty dishes demonstrating invalid cooking. One of the results of the exhibit is that a large number of visitors have inspected the hospital itself during the last few months. Among them many visitors from France have taken advantage of the special permits to view the London Hospital, which can be obtained from the hospital stall at the exhibition. For the benefit of the foreign visitors several special "tours" round the hospital have been arranged for large parties with great success. This medical entente cordiale was further demonstrated by the election of Dr. Lucas-Championnière, consulting surgeon to the Hôtel Dieu, Paris, and senior surgeon at the Beaujon Hospital, to the honorary fellowship of the Royal College of Surgeons of England last Tuesday.

A certain quack institute in England has adopted most audacious methods of advertising. Some of the most eminent medical men in England, in America, and on the Continent are given in a list, and they are stated to approve of the treatment at the institute. The Queen and President Roosevelt are also dragged in. These names are apparently introduced in order to persuade a simple public that the treatment at this institute receives the sanction, approval, or praise of these distinguished individuals. This advertisement has appeared in most of the daily papers, occupying half a page. It is surprising that good class newspapers should lend themselves to such unblushing effrontery and auda-

cious exploitation.

Therapeutical Motes.

The Hypnotics of the Newer Materia Medica. In a recent number of the Pharmascutische Zeitung (No. 33, 1908) there appears a review of two papers which were read before the Congress of Internal Medicine at Berlin, dealing with the newer somnifacients, and the review is abstracted in the American Druggist for August 24, 1908. H. Thoms took up Fraenkel's classification of these substances, which divides them into three groups. The first another which depend for their action on the halogen content the ground upon the presence of an

alkyl, and the third upon an aldehyde or ketone. This grouping is, as Thoms remarks, not strictly applicable, as certain substances are of such combinations as to be classed in more than one of these groups. It forms, however, a working chemical scheme by which the hypnotics may be studied. The first group may be subdivided into two further divisions: (a) the chloral hydrate class, containing also chloralformamide, chloralose, dormiol, hypnal and isopral; and (b) halogen containing acid amides, such as veronal (diethylbromacetamide) and bromural (alphamonobromisovalerianylurate). The second group is also subdivided into (a) alcohols (ethylalcohol and amylene hydrate); (b) methane derivatives of sulphone, as sulphonal, trional, tetronal, and (c) substituted carbamic amides, the derivatives of carbamic acid, as urethane and hedonal (methylpropylcarbinolurethane), and derivatives of urea, as veronal and proponal. The third group, aldehydes and ketones, includes acetaldehyde, acetone (dimethylketone), propion (diethylketone), paraldehyde, and hypnone (acetophenone). In discussing the pharmacological action of these chemical groups, Thoms draws attention to the fact that the halogen compounds (group 1) have been shown to exert a depressing action upon the heart and respiratory system, that the methane derivatives of sulphone, such as sulphonal and trional, have not an innocent record, and finally that evidence is accumulating that veronal and proponal are sometimes injurious, particularly when administered in large doses. He concludes that the ideal hypnotic is yet to be discovered. Ziehen, who treated the subject from the clinical standpoint, stated that the subcutaneous use of these agents had been up to the present unsuccessful, with the exception of the veronallike substances, which could be used without danger, especially in nervous diseases. He advised using a suitable combination of drugs and frequent changes. The ideal procedure, according to Ziehen, was never to prescribe one hypnotic, but always two, and change the proportion of one to the other at intervals. This is naturally not always possible in practice but is a valuable principle to bear in mind.

The Treatment of Chronic Gastritis.—This is the subject of a study by Crämer, who recommends the following bitter tonics to increase the appetite and the gastric secretion. First in order of effectiveness he places condurango, followed by gentian, calumba, quassia, nux vomica, wormwood, tincture of cinchona, and tincture of orange peel, in this order, given in appropriate combinations. Giving preference to condurango he orders the following:

When there is a feeling of pain in the stomach, the gastralgia is overcome by the following mix-

Timeture of helladonna,
Timeture of walerian,
Timeture of valerian,
Al et Sig Twenty drops to be taken in peppermut water two or three times daily.

NEW YORK, SATURDAY, SEPTEMBER 26, 1908.

PLAGUE INVESTIGATIONS IN INDIA.

The May number of the Journal of Hygiene constitutes a fourth extra plague number. It contains further reports of the work of the investigators who have been studying the problems connected with the present epidemic of bubonic plague, under the auspices of the Advisory Committee. The former plague numbers have been commented upon in these columns; the present number begins with the publication of the translation of a paper written in 1902-'03 and presented as a thesis for the degree of doctor of medicine to the University of St. Petersburg in 1904. This paper, which is entitled The Part Played by Insects in the Epidemiology of Plague, written by Dr. D. T. Verbitski, goes over the ground subsequently covered by the workers of the Advisory Committee. The next report is by Dr. Bannerman and Dr. Kápadiâ, on experiments to discover whether the common domestic animals of India are affected with plague. Pigs, calves, fowls, turkeys, geese, and ducks were fed with the flesh of rats that had died of plague, but in no instance was plague contracted by the animals. These results entirely reverse those obtained in Hongkong in 1902 by Simpson. The suggestion is made in the report that Dr. Simpson's animals were suffering with an infection with the hog cholera bacillus.

The next paper, which is anonymous, details additional observations on the septicæmia of human plague and gives an account of experiments on the infectivity of the excreta. It is found that a severe

septicæmia may be present at a comparatively early stage of the disease, and that it is surely present for a number of hours before death. This septicæmia increases, as a rule, as death approaches, and is in direct relation to the acuteness of the illness. It may be progressive, diminishing, irregular, or fluctuating. Virulent Bacillus pestis may be excreted in the urine of patients with plague; but the urine and the fæces of such patients are not capable of transmitting plague in the natural way. After a paper on the bionomics of fleas, a description of the mechanism by means of which the flea clears itself of plague bacilli appears. The investigators of this subject found that a clearing process, which is more active at 90° F., existed, which is probably of a phagocytic nature. The seasonal prevalence of plague was studied in six different places in India, places widely separated and subject to different climatic conditions. It was found that the rat epizootic and the human epidemic depended upon a suitable mean temperature, somewhat below 85° F., and in general over 70° F.; a sufficient number of susceptible rats; and a sufficient number of rat fleas. A fall of the rat epizootic, and consequently of the human epidemic, is determined by a high mean temperature. above 85° F., a diminution in the total number of rats, an increase in the proportion of immune to susceptible animals, and a diminution in the number of rat flees. The number ends with a paper on the distinction of Bacillus pestis from certain allied organisms, such as Bacillus pseudotuberculosis rodentium, bacilli of the hæmorrhagic septicæmia group, and organisms of the Bacillus enteritidis group.

DEATH FROM OLD AGE.

All multicellular organisms, plants and animals, have only a limited period of life, some longer, some shorter, but all must die. Men can reach an age of a hundred or a few more years, but after the vigor of full manhood man's faculties decline, he becomes a senile person, of no more use to society, and finally dies.

But why death, why must all organisms die, including man? And why do the different species of organisms have different limitations to the period of life? These questions are as old as thinking man himself; they have often been discussed; much has been written about them; and many investigations have been and will be made without finding even a partially satisfactory answer. But every new effort to solve this riddle is of great attraction.

Dr. Hugo Ribbert, professor of pathology in the University of Bonn, has written a pamphlet on the subject. He does not produce any new theories or bring us nearer to our goal, but he reviews our pres-

ent knowledge thoroughly and gives us the different theories in a very scientific manner, giving a résumé which is very interesting to read. It is peculiar that at about the same time there appeared in Germany another book on this subject, entitled Todes Prognosen, oder Wann stirbt der Mensch? by A. A. Michaeles, but in such a contrast to Dr. Ribbert's essay, so unscientific, that one can hardly understand how any sane man could write or publish such nonsense.

But, to come back to Professor Ribbert's book. He reminds us that all the cells of our body are capable of regeneration and rejuvenation, with the exception of the ganglion cells of our central nervous system and of the sympathetic and the germ cells, which latter cells have nothing to do with the question of death. These general bodily cells are in a perpetually regenerating and rejuvenating condition, while, according to our present knowledge, the ganglion cells remain the same from earliest youth, whether they belong to a brain for eighty, ninety, or a hundred years. They are always the same elements. Sooner or later it will be found that the general bodily cells do not possess their former vitality; there will appear changes in their development, their life, their multiplication, their protoplasm, and their nuclei, and, finally, their action, changes which appear from within, resulting in the end in atrophy of the several organs. But for a longer or a shorter period these cells possess the faculty of being rejuvenated, while the ganglion cells lack this power. This can also be demonstrated by transplantation; it is possible to transplant, not only parts of organs, but also entire organs, and these transplanted structures will live in their new surroundings; but not so with the brain or parts of the brain, for transplantation of brain matter is always unsuccessful. The heart possesses such rejuvenating cells, and, next to the brain, if is the most important organ of the body. The ganglion cells, not having the power of rejuvenation, will be the first cells to cease to be able to perform their functions properly. This shows that the brain, or rather the central nervous system, is the first organ which, in natural death, begins the process of death, and, by its ceasing to live, is the prime cause of natural death, proved also by the appearance of natural death, the increasing psychic debility, the gradually falling asleep, etc., while the other organs, especially the heart, retain their functions for a for or time, until they also become impaired and

This is the great distinguishing feature between physiological and pathological death. In pathological death the general cells cease to possess their properties to prove the content of t

teria or toxines), and the heart will cease to perform its function, while physiological death is mostly the result of failure of the brain (central nervous system).

Natural death in senility is therefore a sequence of anatomical and, with them, functional changes of the component factors of the body, partly the cells, partly the intermediate substances. These changes in physiological death are not the result of external influences (too much or improper food, disease producing influences, such as toxines, according to Metchnikoff's theory), but they are the necessary sequelæ of the chemical and physical expiration of the phenomena of life. In the cells are formed clinkers, so to speak, deposits which are a product of metabolism, which produce atrophy of the protoplasm. The intermediate substances, which in the real sense of the word are not living matter, commence to gradually relax in their more or less mechanical functions, thus damaging the blood circulation. This fact, again, is of detriment to the cells, the atrophy of which is then increased. Diseases of senility, especially arteriosclerosis, will favor the accomplishment of the conditions of old age, but they do not belong as such to senility; they are only complications. Old age as such is free from diseased conditions. Of the cells of the body, the ganglion cells are especially responsible for natural death in old age. Physiological death is therefore more or less a brain death.

THE UNTOWARD EFFECTS OF COR-ROSIVE SUBLIMATE.

Pursuing his very practical consideration of the undesirable effects of various surgical antiseptics, which we have mentioned in previous issues, M. Salva Mercadé (Archives générales de médecine, July) takes up the subject of the occasional toxic action of corrosive sublimate. A somewhat prolonged application of a solution of mercuric chloride to the skin, he remarks, produces thickening and induration of the integument. In rare instances a faint erythema results, and in some cases the erythematous area is covered with vesicles.

It is uncommon for the absorption of corrosive sublimate from a traumatic surface to be carried to the extent of producing systemic poisoning. Brun, however, gives the history of a case in which signs of toxic action appeared on the sixth day after an operation by Bakelman for prolapse of the rectum and vagina, the patient having been treated with douches and lotions of a one to one thousand solution. The woman felt a burning sensation in the mouth, and salivation and gingivitis were noted.

These symptoms subsided in three days. Longuet (cited in Zimmer's *Thèse de Paris*, 1907) observed a metallic taste in the mouth, with ptyalism, after five minutes' immersion of the hands in a corrosive sublimate solution. Mercadé does not inform us of the strength of the solution. Possibly idiosyncrasy or self suggestion had something to do with producing the results mentioned.

In the grave cases of general poisoning the whole digestive canal suffers, and we observe salivation, sponginess and ulceration of the gums, gangrenous patches, vomiting, colic, and diarrhœa. The pulse is small, and there is albumin in the urine. Often, too, there are extensive eruptions. Such cases have been recorded by Maurer and Reichel. Ruggi, of Bologna, saw a woman die rapidly in collapse after an operation for a fibrous tumor; by inadvertence the compresses had been soaked in a solution of corrosive sublimate. But such occurrences are rare. As a general thing, untoward results are produced only when one of the natural cavities of the body is irrigated with the solution or when it is used in ragged wounds, so that some of the liquid is retained. In all instances the poison must be eliminated as soon as possible by mean of diuretics, the stomatitis may be combated with potassium chlorate, and collapse should be met with injections of ether and caffeine.

THE DIRTY STREETS OF PARIS.

Here in New York we are accustomed to the reproach of neglecting to keep the streets clean. The charge is not undeserved, and the tu quoque retort does not relieve us of blame. Nevertheless, it is consolatory to find distinguished Parisian authority for the statement that the French capital is one of the dirtiest cities in the world. The Progrès médical, in its issue for September 12th, so declares, and it finds one of the great causes of the uncleanliness of the streets to be the extent to which waste paper is thrown upon the pavements. Handbills, it appears, are distributed to pedestrians in great numbers, and they are cast aside in almost total disregard of the baskets provided in the parks and squares as receptacles of waste paper. Almost every inhabitant, says our contemporary, takes a newspaper and reads it at home, and many papers are read in the streets also, only to be cast to the ground when they have been read.

We have long been accustomed to this broadcast scattering of newspapers in the streets of New York. It was one of the difficulties with which the late Colonel Waring had to contend. His fertility in resources was severely taxed by the carelessness of our people in the matter of waste paper, but he met the problem with a device which is still in

advantageous use. The New Yorker without his newspaper is like the *Bayern ohne Bier*. His ways of making himself a nuisance with the aid of his paper are multifarious, but the final disposition which he makes of it leads now to far less trouble than it did formerly, thanks to Colonel Waring's device, to the boxes established for the benefit of hospital inmates, and to the avidity with which cast off newspapers are gathered up by the employees on public conveyances.

But it is not littering with paper only that interferes with the cleanliness of the Paris streets, according to our contemporary. Too many of the municipal street cleaners, it declares, are either superannuated, infirm, or lazy, more industrious at tippling than at plying the broom, and the result is that the streets are dirty. Nevertheless, says the Progrès, extravagant sums of money are spent by the city of Paris for the purpose of cleaning the streets. The personnel of the street cleaning force, it suggests, ought to be reformed. Younger men should be employed, and their ambition should be stimulated by the prospect of promotion as the reward of good work. Our contemporary points to Berlin as a capital in which excellent work is done in the matter of street cleaning. It is to be feared that New York is not yet worthy of being pointed out as a shining example of cleanliness.

THE PUBLIC HEALTH AND MARINE HOS-PITAL SERVICE.

We have always contended that confirmation and extension of the powers of this bureau were much to be preferred to any other means of nationalizing the sanitary activities of the country. We are glad to see that the same view has been taken by the American Public Health Association, as was shown by a resolution adopted at its recent Winnipeg meeting, for the text of which we refer our readers to the Toronto letter published in our last issue. The bureau has done excellent service in the past, and we believe that in its organization is to be found the best means of performing the sanitary service, both foreign and domestic, that the country needs.

STRIÆ ATROPHICÆ FROM VARIOUS CAUSES.

In the September number of the *Practitioner Dr.* F. Craven Moore records a case of striæ atrophicæ of the back discovered on the fifth day of convalescence from double pleuropneumonia in a lad, nineteen years old. They were transverse in direction and were situated in the dorsolumbar region of

each side, corresponding approximately to the course of the posterior branches of those dorsal nerves which would be related to the diseased areas. He has found in literature the record of only one other case following pneumonia. He finds that atrophic stripes are occasionally met with after typhoid fever, over the patellæ, on the outer sides of the lower limbs, and occasionally on the abdomen. They have been observed, too, after appendicular inflammation, after scarlet fever, in connection with malignant disease of the pleura and peritonæum, and in young adults without apparent cause. He suggests that there must be causes for their appearance which are not of a mechanical nature.

Rems Atems.

Changes of Address.—Dr. William S. Wray, from 114 South Eighteenth Street, to 2007 Chestnut Street, Philadei-

Personal.—Dr. Samuel M. Brickner has returned to New York, and resumed practice at 130 West Eighty-fifth

The Medicochirurgical College of Philadelphia inaugurated its session for 1908-1909 on Monday, September 28th. Dr. L. Webster Fox delivered the address.

A Bronze Bust to Dr. Byron Robinson.-Dr. Byron

A Bronze Bust to Dr. Byron Robinson.—Dr. Byron Robinson's students are planning to erect a bronze bust to him. Dr. Benjamin Orndorff, 2277 Wilcox Avenue, Chicago, has the matter in charge.

St. Joseph's Hospital's New Isolation Ward.—The new isolation ward of St. Joseph's Hospital, Philadelphia, was dedicated on Thursday, September 24th. The ward will be known as St. Edmund's ward, and will be devoted on the study and treatment of containing diseases. entirely to the study and treatment of contagious diseases.

Contagious Diseases in Chicago.-During the week ending September 12, 1908, there were reported to the Department of Health 228 cases of contagious diseases, as follows: Diphtheria, 54 cases; scarlet fever, 70 cases; measles, 6 cases; chickenpox, 3 cases; pneumonia, 8 cases; whooping cough, 16 cases; tuberculosis, 28 cases; others, of minor

The Lewis County, N. Y., Medical Society.—A meeting of this society was held in Lowville, N. Y., on September 14th. There was a large attendance of members, and many visitors were present. The principal feature of the programme was a paper on Appendicitis, read by Dr. G. D. Gregor, of Watertown. At the close of the meeting a banquet was served at the Kellogg House.

The St. Tammany Parish Medical Society, New Or-

leans.—This society was reorganized recently, and officers elected as follows: President, Dr. G. R. Tolson; vice president, Dr. R. B. Paine; secretary, Dr. J. F. Pigott; treasurer, Dr. P. R. Outlaw. Every physician in the parish is expected to join the association, which meets once a mooth, on the birst Wednesday of the month

Richmond, Va., Academy of Medicine and Surgery. At the regular monthly meeting of this academy, which was held on Tuesday, September 22d, Dr. Wilhelm Karo, of Berlin, Germany, read a paper on Tuberculosis of the Bladder. In the afternoon a clinic was held at the Memorial Hospital, at which Dr. Karo performed a suprapubic

prostatectomy under spinal anæsthesia.
Union of Old German Students in America.—The Philadelphia branch of this organization held a reception ciety on the evening of Wednesday, September 23d, in honor of the many celebrated physicians from foreign countries who have come to the United States to attend the Countries who have come to the United States to attend the International Congress on Tuberculosis. Among the invited guests were Dr. Robert Koch, Dr. v. Leube, Dr. Pannwitz, Dr. Helm, Dr. v. Pirquet, Dr. v. Schroetter, Dr. Rumpf, Dr. Kirchner, Dr. Spengler, Dr. Calmette, Dr. Maragliano, and Dr. Fibiger.

The International Association for the Investigation of Cancer.-Professor von Leyden, of Berlin, has been of Cancer.—Professor von Leyden, of Berlin, has been elected homorary president of this association, which was established in Berlin in May. Professor von Czerny, of Heidelberg, has been elected president, and the vice-presidents of the association are Professor Pierre Marie, of Paris, and Professor Fibiger, of Copenhagen.

The Medical Corps of the Army.—The recent examination for first lieutenants in the Medical Corps of the Illied States Army resulted in the annoniment of themps.

United States Army resulted in the appointment of twenty successful candidates. Of the one hundred and fifty candidates who made application, only eighty-three qualified in the physical examination. The young men who passed the examination will enter on a course of instruction at the Army Medical School on October 1st.

The Northern Medical Association of Philadelphia .-A stated meeting of this organization was held on Friday A stated fleeting of this organization was field on Friday evening. September 25th. The programme included the following papers: Ætiology and Treatment of Sterility in the Female, by Dr. W. E. Parker; Ætiology and Treatment of Sterility in the Male, by Dr. Orville Horwitz. The discussion was opened by Dr. Charles P. Noble, Dr. Brooke M. Ap. 3h and Dr. Orville Horwitz

The Mortality of New Orleans .- During the month of August, 1908, there were reported to the Board of Health of the City of New Orleans 504 deaths from all causes, 301 white and 203 colored. The annual death rate in 1,000 of population was 14.00 for the white population, 26.19 for the colored, and 17.23 for the total white and colored. There were 58 still births, 30 males and 28 fecolored. There were 58 still births, 30 mars males. The total infant mortality was 81; under one year of age, 70; between one and two years, 11.

following apointments have been made to the staff of the Division of Pharmacology of the Hygienic Laboratory: Dr. W. H. Schultz, instructor in physiology and pharmacology at the University of Missouri; Dr. Worth Hale, instructor in pharmacology at the University of Michigan; Mr. M. I. Wilbert, of the German Hospital, Philadelphia; and Dr. M. G. Motter, professor of physiology at the Georgetown University

Medical Society of the County of Kings, N. Y.—A meeting of the Section in Padiatrics was held in the Library Building, 1313 Bedford Avenue, Brooklyn, on Friday brary Building, 1313 Bedford Avenue, Brooklytt, on Friday evening, September 18th. The programme included the report of a case of congenital heart, presented by Dr. F. B. Van Wart, and a paper entitled The Blood in Infancy and Childhood, by Dr. A. D. Smith. The officers of this section are as follows: Dr. Archibald D. Smith, chairman; vice chairman, Dr. John W. Parrish; secretary and treasurer, Dr. William H. Woglom.

The Hartford, Conn., Medical Society.-The Surgical Section of this society will meet on Monday evening, September 28th. Dr. A. J. Wolff will report an unusual case of abdominal pregnancy. Dr. Oliver C. Smith will present instructive specimens from recent operations. Dr. H. G. Howe will report a case of dislocation of the shoulder with double fracture of the humerus. Observations of interest noted in foreign hospitals will be the subject of papers to be read by Dr. William Porter, Jr., Dr. W. G. Murphy, Dr. J. W. Felty, and Dr. J. B. Boucher.

Society Meetings for the Coming Week:
MONDAY, September 28th.—Medical Society of the County
of New York.

THURSDAY, October 1st.—New York Academy of Medicine; Dansville, N. Y., Medical Association.

FRIDAY, October 2d.—New York Academy of Medicine (Section in Surgery; New York Microscopical Society; Gynacological Society, Brooklyn, N. Y.; Manhattan Clinical Society, New York; Practitioners' Society, New York; Practitioners' ciety of New York.

St. Agnes's Hospital for Crippled and Atypical Children.—The Sisters of St. Francis have established a hospital at White Plains, N. Y., for the treatment of cripples and mental defectives. The property, which was formerly the Westchester County Temporary Home, conformerly the westchester County Temporary Home, consists of sixteen acres, with modern buildings well adapted for hospital purposes. It will have accommodations for one hundred and fifty patients, and will be supported by volutary contributions. Applications for admission may be made to Dr. John Carling, 120 Fast Thirty fourth Street, New York.

Scientific Society Meetings in Philadelphia for the Week Ending October 3, 1908:

Monday, September 28th,—Mineralogical and Geological Section, Academy of Natural Sciences. Section,

THURSDAY, October 1st.—Obstetrical Society; Medical Society of the Southern Dispensary; Section Meeting. Franklin Institute; Germantown Branch, Philadelphia County Medical Society.

FRIDAY, October 2d.—American Philosophical Society; Kensington Branch, Philadelphia County Medical So-

ciety.

The Medical Society of the State of Pennsylvania held its annual meeting in Cambridge Springs, Pa., on Monday, Tuesday, Wednesday, and Thursday, September 14th to 17th. The following officers were elected: President, Dr. George W. Wagoner, of Johnstown; vice presidents, Dr. James I. Johnson, of Pittsburgh; Dr. Glennis E. Humphrey, of Cambridge Springs; Dr. Howell M. Gates, of Scranton, and Dr. Samuel Z. Shoate, of Harrisburg; secretary, Dr. Cyrus L. Stevens, of Athens; assistant secretary, Dr. Theodore B. Appel, of Lancaster; treasurer, Dr. C. M. Harris, of Johnstown; trustees, Dr. George W. Guthrie, of Wilkesbarre, Dr. George W. Drutt, of Wilkesbarre, Dr. Georger D. Nutt, of Williams-Guthrie, of Wilkesbarre, Dr. George D. Nutt, of Williamsport, and Dr. J. H. Wilson, of Beaver. Bedford Springs was selected as the next place of meeting.

was selected as the next place of meeting.

Philadelphia County Medical Society.—The Central Branch of this society held a meeting on Wednesday evening, September 9th. The programme consisted of a "symposium" on exophthalmic goitre. Papers on the subject were read by Dr. Edward J. G. Beardsley, Dr. George A. Müller, Dr. William Zentmayer, Dr. W. Wayne Babcock, Dr. George Pfahler, and Dr. Robert N. Willson. At a meeting, bald on September, and the avening way desired. meeting held on September 23d the evening was devoted to a consideration of the question of the division of the fee. Dr. John H. Gibbon read a paper dealing with the question from the viewpoint of the surgeon. The internquestion from the viewpoint of the surgeon. The internist's point of view was the subject of a paper by Dr. Solomon Solis-Cohen, and the general practitioner's opinion of the evil was discussed in a paper by Dr. M. H. Fussell,

The Tri-Professional Medical Society of New York .-The second annual meeting of this society was held at the Hotel Astor, New York, on September 15th. The programme included the annual address of the president, J. Monroe Lieberman, and the following papers: Electricity—An Indispensable Therapeutical Agent in Nervous, Dermatological, and Genitourinary Diseases, by Dr. J. Monroe Lieberman; Sequelæ due to Nonremoved Adenoids Monroe Lieberman; Sequelæ due to Nonremoved Adenoids in Childhood, by Dr. Arthur J. Herzig; Sexual Anæsthesia in Women, by Dr. B. S. Talmey. Among those who participated in the discussions were Dr. G. M. MacKee, Dr. T. M. Townsend, Dr. Augustine Goelet, Dr. M. C. O'Brien, Dr. George Lesser, Dr. H. B. Sheffield, and Dr. J. Sohl. A resolution was adopted by the society censuring Governor Hughes for signing the osteopathic bill. While on his way to attend the meeting, Dr. G. B. McAuliffe fell from a street car and sustained a Pott's fracture of the

The Mortality of Chicago. During the week ending September 12, 1908, there were reported to the Department of Health of the City of Chicago 556 deaths from all causes, as compared with 553 for the previous week and 570 for the corresponding period in 1907. The annual death rate in 1,000 of population was 13.38, as against a death rate of 13.31 for the corresponding week last year. Of the total number of deaths 239 were of children under five years of age, and of these 136 were due to diarrhocal diseases. The principal causes of death were: Apoplexy, 12 deaths; Bright's disease, 33 deaths; bronchitis, 11 deaths; consumption, 66 deaths; cancer, 22 deaths; diphtheria, 12 deaths; heart disease, 30 deaths; intestinal diseases, acute, 144 deaths; nervous diseases, 24 deaths; pneumonia, 24 deaths; scarlet fever, 10 deaths; suicide, 7 deaths; typhoid fever, 5 deaths; violence (other than suicide), 20 deaths; whooping cough, 4 deaths; all other causes, 132 deaths

The Health of Philadelphia .- During the week ending September 12, 1908, the following cases of transmissible diseases were reported to the Bureau of Health: Malarial fever, I case, o deaths; typhoid fever, 78 cases, 12 deaths; scarlet fever, 16 cases, I death; chickenpox, 2 cases, o deaths; diphtheria, 55 cases, 12 deaths; measles, 12 cases, 1 death; whooping cough, 5 cases, 2 deaths; tuberculosis of the lungs, 71 cases, 52 deaths; pneumonia, 19 cases, 13 deaths; crysipelas, 1 case, 0 deaths; puerperal fever, 2 cases, o deaths; cancer, 22 cases, 27 deaths. The following deaths were reported from other transmissible diseases. Tuberculosis, other than that of the lungs, 12 deaths; diarrhea and enteritis, under two years of age, 44 deaths; dysentery, 2 deaths; cholera morbus, 2 deaths. The total deaths numbered 445 in an estimated population of 1,532,-738, corresponding to an annual death rate of 15.01 in 1,000 736, corresponding to an annual death rate of 15.0 in 1,300 in 1,300 for population. The total infant mortality was 115; under one year of age, 96; between one and two years of age, 19. There were 27 still births, 17 males and 10 females.

Charitable Bequests.—By the will of William J. Eavenson, the Home of the Merciful Saviour for Cripble (Children of Dividately). The Philodolphis Home for Inc.

Children, of Philadelphia, the Philadelphia Home for fants, and the Home for Consumptives, of Philadelphia,

By the will of Mrs. Jane A. Townsend, who died recently in England, the Presbyterian Hospital, New York, will receive \$15,000 to endow three free beds in memory of two sons and a daughter, deceased. The Presbyterian Home for Aged Women in the City of New York will receive \$34,500.

By the will of George F. Parkman, the Massachusetts General Hospital, Boston Home for Aged Women, Boston Home for Aged Men, Children's Hospital, and the McLean Home for Aged Men, Children's Hospital, and the McDean Insane Hospital will each receive \$5,0,000. Provisional bequests are made of \$100,000 to the Massachusetts Institute of Technology, and \$20,000 each to the New England Hospital for Women and Children and the Massachusetts Charitable Eye and Ear Infirmary.

By the will of Henry J. Braker, who died recently in Plymouth, England, St. John's Guild, New York, receives \$10,000 to create a Conrad Braker, Jr., Fund, the income of which to go to the floating hospital fund of that institution. The Sheltering Arms, 504 West 129th Street, receives \$10,000 to erect a cottage in memory of Mr. Braker's mother, to be known as the Frances J. Braker Cottage.

The Cholera Epidemic.—According to press despatches there is no improvement in the cholera situation in Russia. In St. Petersburg the epidemic is reported to grow worse daily, and hospital facilities are said to be entirely inade-quate to meet the requirements. It is reported that five hospitals will be opened immediately, and the number of ambulances, disinfectors, and physicians increased. The disease is also spreading in the Provinces.—In the Philippines the vigorous measures of inspection, disinfection, and increased hospital facilities carried on by the authorities seem to have resulted in an improvement in the cholera situation there. The work is still being carried on, and it is hoped that Manila will soon be freed from the disease.-Every preparation is being made to deal with the epidemic should it make its appearance in Germany. A conference of representatives of the Imperial Department of Health, the Department of the Interior, and the Army and Navy was held on September 22d to consider the cholera situation. It is feared that the disease has already reached Berlin, and a number of suspected cases of cholera are under supervision at the Virchow Hospital,—France is also taking precautions against the disease gaining a foothold there. Emergency ambulance stations and disinfecting plants have been established at the terminals of the northern and eastern railroads, and a rigid inspection of all baggage is insisted upon. Orders have been issued that all vessels from the Russian Baltic bound for French ports are to be thoroughly disinfected.—Every precaution is being taken to prevent the sailors of the Atlantic Fleet from being exposed to cholera in the Philippines. Before the fleet reaches Manila a wireless message will be sent to Admiral Sperry regarding the cholera situation at that time. and giving him instructions how to proceed under the conditions then prevailing.

Vital Statistics of New York .- During the week ending September 5, 1908, there were reported to the Department of Health of the City of New York 1,321 deaths from all causes, as compared with 1,402 for the corresponding period in 1907. The annual death rate in 1,000 of population was 15.58. There were 654 deaths reported in Manhattan, 108 in the Bronx, 450 in Brooklyn, 87 in Queens, and 22 in Richmond. Of the total number of deaths 509 were of children under five years of age, and of these 244 were due to diarrhœal diseases. There were 115 still births. Seven hundred and eighty-six marriages and 2,384 births were reported during the week.

During the week ending September 12, 1908, there were for the corresponding period in 1907. The annual death rate for the corresponding period in 1907. The annual death rate in 1,000 of population was 14.38. Of the total number of deaths 625 were in Manhattan, 120 in the Bronx, 393 in Brooklyn, 56 in Queens, and 25 in Richmond. There were 438 deaths reported of children under five years of age, and of these 203 were due to diarrheal diseases. There were 138 still births. Nine hundred and seventeen marriages and 2,332 births were reported during the week.

The International Congress on Tuberculosis.-This The International Congress on Tuberculosis.—This congress, which meets triennially, was formally opened in Washington, D. C., on Monday, September 21st. It will continue for three weeks, closing on Monday, October 12th. More than fifteen hundred official delegates have been appointed, representing nearly every civilized country in the world. Each of the forty-six States of the Union is reported. resented by its own committee, and among the foreign countries which have sent delegates are the following: Argentina, Austria, Belgium, Bolivia, Brazil, Bulgaria, Chile, Colombia, Costa Rica, Cuba, Denmark, Ecuador, France, Germany, Great Britain (including her more important dominions and colonies), Greece, Hawaii, Holland, Hungary, Italy, Japan, Mexico, Norway, Panama, Peru, Portugal, Puerto Rico, Roumania, Russia, San Salvador, Siam, Spain, Sweden, Switzerland, Syria, Uruguay, and Venezuela. The transactions of the congress will be published in four large volumes, which are forces to all active members of the congress. volumes, which are free to all active members of the conrolumes, which are tree to all active members of the congress who have paid their membership fee of \$\frac{8}{5}\$. The congress is divided into seven sections, and the meetings of these sections will be held in the New National Museum during the week begining September 28th. The sections are as follows: (1) Pathology and Bacteriology, Dr. William H. Welch, of Baltimore, president; (2) Clinical Study and Therapy of Tuberculosis, Dr. Vincent Y. Bowditch, of Boston, president; (3) Surgery and Orthopædics, Dr. Charles H. Mayo, of Rochester, Minn., president; (4) Tuberculosis in Children, Dr. Abraham Jacobi, of New York, president; (5) Hygienic, Social, Industrial, and Economic Aspects of Tuberculosis, Mr. Edward T. Devine, of New York, president; (6) State and Municipal Control of Tuberculosis, Surgeon General Walter Wyman, of Washington, D. C., president; (7) Tuberculosis in Animals and Its Relation to Man, Dr. Leonard Pearson, of Philadelphia, president. A tuberculosis exposition is being held in the New National Museum, which is practically a World's Fair on Tuberculosis. Clinics and demonstrations will be held in connection with this exhibition, which will be open during the entire time. Prizes, in the form of money, medals and diplomas, will be awarded for exhibits that are particularly meritorious. President Rosewell is president of the Congress, Dr. Edward L. Trudeau, of Saranac Lake, to be provident and Wise President series and the proper decident and Wise President series and the proper decident series and the congress, Dr. Edward L. Trudeau, of Saranac Lake, to be president and Wise President series and the proper decident series and the president for the proper deciden gress who have paid their membership fee of \$5. of the Congress, Dr. Edward L. Trudeau, of Saranac Lake, is honorary president, and Vice-President Fairbanks, is honorary president, and Vice - President Fairbanks, Speaker Cannon, and the governors of States are the vice-presidents. Dr. John S. Fulton, of Washington, D. C., is secretary general. The other officers of the congress are soflows: Dr. Lawrence F. Flick, of Philadelphia, chairman of the Central Committee; Dr. Joseph Walsh. of Philadelphia, secretary; Mr. Henry Phipps, of New York, treasurer; Dr. Henry G. Beyer, of Washington, chairman of the Committee on Exhibition; Dr. Charles J. Hatfield, of Philadelphia, chairman of the Committee on Prizes; Dr. George M. Kober, of Washington, chairman of the Committee on Special Lectures; General G. M. Sternberg, of Dr. H. M. Bracken, chairman of the Transportation Committee; Dr. Joseph Walsh, of Philadelphia, chairman of the Committee on Translation and Interpretation; Dr. Livingston Farrand, of New York, chairman of the Committee on Printing and Publication; Dr. Lawrence Litchield, of Pittsburgh, chairman of the Committee on Entertainment.

Bith of Current Miterature.

THE BOSTON MEDICAL AND SURGICAL JOURNAL. September 17, 1908.

- Nontuberculous Bone Infection about the Hipjoint. A
 Clinical and Röntgenological Study,
 By Arrhur T. Leca and Urial W. George.
 An Analysis of the Symptoms in Forty Cases of Suppuration of the Kidney or Kidney Pelvis.
- The Necessity of Disinfection after the Death or Removal of Tuberculous Patients, By Henry Jackson.

 State Sanitary Supervision, By Herrer Ackson.
- Nontuberculous Bone Infections about the Hipjoint.-Legg and George remark that pyogenic infection of the bone, though it may occur in the epiphysis, most commonly takes place in the diaphysis. Osseous infection of the tubercle bacillus, on the other hand, occurs in the epiphysis with but few exceptions. One of these occurs in children at an age when there is no osseous epiphysis; another, by direct infection from a focus in the epiphysis. Clinically, the symptoms of acute pyogenic infections outside the hipjoint, namely, acute onset, rapid thickening of the neck, trochanter, or upper shaft, pain, spasm, and constitutional symptoms with high white count, will generally easily distinguish this class from tuberculosis. The distinctive diagnosis of the chronic cases, those produced by a low grade organism, is, however, much more difficult from a clinical standpoint. The deformity, limitation of motion, spasm, and atrophy may be the same as that seen in tuberculosis of the hip. Thickening is felt earlier than in tuberculosis, and the white count is considerably higher than we find in uncomplicated tuberculosis. There may be no more constitutional symptoms in this class of cases than is seen in tuberculosis. Of all points in the physical examination of cases referable to the hipjoint, rotation is of the greatest importance. In cases with a focus outside the hipjoint, rotation may be free, limited, or even absent. If any is present, however, it will have the normal quality, while, where any change has taken place in the articular cartilage, the rotation, if present, has a peculiar characteristic quality. In the acute pyogenic infections within the joint there are classical symptoms of acute joint infection, acute onset, rapid joint distention, pain, constitutional disturance, and high white count. The subacute or chronic cases, those starting in the epiphyseal line or as a general joint infection, may differ in no respect clinically from tuberculous hip disease. These will generally clear up much earlier than tuberculosis, with possible perfect function. This type will show an ultimate permanent lengthening from the irritation of the epiphyseal cartilage. It is thus seen that although acute extraarticular and intraarticular pyogenic bone infections may be made clinically, the subacute or chronic cases cannot, early at least, be distinguished from tuberculosis. Here we must use the Röntgen ray to show the exact location and the extent of the process.
- 2. Suppuration of the Kidney or Kidney Pelvis. Chate gives the following symptoms for suppuration of the kidney or kidney pelvis: Less than one balf of the patients in his series, 42.5 per cept give a history of humbar pain. In only a lit-

tle more than one fourth, 28.5 per cent., could he make out any enlargement of the diseased kidney. Tenderness was present in 38.5 per cent. Casts, on which some place much importance, appeared in but 17.5 per cent. A very striking thing to him was the fact that eleven of these forty cases, 27.5 per cent., presented neither pain, renal mass, tenderness, nor casts. From an analysis of his forty cases it appears that we have in suppurations of the kidney and kidney pelvis but one sign that is always present, that is, a turbid urine. The next most frequent sign, present in 85 per cent. of the cases, was a disturbance of micturition; both these symptoms also occur almost constantly in conditions limited to the bladder. There was a considerable proportion of renal suppuration, 27.5 per cent., in which we get only these two signs. This brings the author to the points that he wishes to emphasize, first, the lack of distinctive symptoms in many renal suppurations; second, the absolute unreliability of negative findings in these cases; last, the tremendous importance of the use of the cystoscope in the study of urinary suppurations.

1. Criminal Abortion in Its Broadest Sense .-Dorsett, in his address as chairman of the Section in Obstetrics and Diseases of Women, states that self induced abortion, or abortion produced by a fashionable or fad doctor, is, as we know, a fruitful cause of the horrible pus cases in which we are now and then called to operate. This fad doctor is one with a lucrative practice, and is often the lion at social functions. He it is who empties the uterus in cases of emesis gravidarum without first racking his precious brain in trying all recognized remedies and methods to check the vomiting. He it is who finds so many cases of contracted pelvis where it is

utterly impossible to do anything but an early abortion to save the woman's life. He it is who finds so many cases of retention of menses that require dilatation and curettement. He it is who finds the urine loaded with albumin, necessitating an immediate emptying of the uterus to prevent death from Bright's disease. Such men and women prostitute the profession of medicine and should be exposed.

4. Diphtheritic Genital Infection Simulating Puerperal Fever.—Cuthbertson remarks that it is, unfortunately, the almost universal custom to call every septic fever occurring during the puerperium puerperal fever, and this arises from the fact that bacteriological examinations are not made often enough to determine the exact cause of the fever, and thus properly to classify the variety of the disease. In the light of our present knowledge, it is as manifestly improper to call a diphtheritic genital infection in the puerperal woman puerperal fever as it would be to call a malarial infection occurring during the same period by a similar name. We know that true puerperal sepsis is one of the most fatal infections we are called on to treat, while diphtheritic infection, if recognized early, is one of the most hopeful. Early recognition of the disease by bacteriological examination, and the resort to antidiphtheritic serum, should enable us to cure every one of these cases, and thus contribute materially to the reduction of the mortality at this critical period of woman's life. The diphtheria invasion does not seem to have any definite period after confinement for making its appearance, the time varying from the third to the twenty-sixth day. Pain in the genitals is apparently one of the prominent symptoms. The membrane covering the genitals is grayish white in color, with a red coloration around the edges. In all but one of the reported cases its appearance was accompanied by fever, ranging from 100° F. to 104° F., with a corresponding acceleration of the pulse. After the favorable experiences in the use of the diphtheria antitoxine serum in the cases reported, there is no doubt that in all patients suffering from diphtheritic puerperal infection, where the Klebs-Loeffler bacillus has been demonstrated, diphtheria antitoxine is a specific for the disease. Curettement, either with a sharp or dull curette, or with the finger, should be scrupulously avoided, as the membrane being densely adherent, its removal results in leaving raw surfaces which serve as open avenues for the absorption of a greater amount of toxic material.

5. Genital Tuberculosis.-Martin describes his experience with genital tuberculosis. He observes that in the large majority of cases the infection arises from other tuberculous deposits in the bodya secondary form-more frequently it seems to come from the alimentary tract rather than from the respiratory. In most instances, the bacillus may be brought down in the lymphatics or blood vessels, but we know that immigration does occur also by means of immediate contact. In more than two thirds of his cases it came from the ovarian follicles to the Falloppian tubes; to the uterus in only one It was also found in the corpus uteri. Localization in the cervix is very rare, still more than in the vagina. Peritoneal infection was observed in the majority of cases. The infection may

occur at any age, but particularly during the menstruation and gestation periods. The clinical diagnosis in most instances is made with difficulty. In fact, the insignificance of the symptoms is characteristic. Menstruation, in his material, was disturbed in only fifty-five per cent.; more or less aching feeling was complained of; many patients denied all such. Some complained of a reddish colored, offensive discharge. They feel uncomfortable, weak, unable to work, lose flesh, and show an unsatisfactory complexion. The sexual appetite not rarely seems to be increased. Not very rarely this disease arises from a well noted incident, puerperium, abortion, gonorrheeal infection, local treatment. A severe cold was often mentioned, particularly in virgins and sterile women. In fact, seriously developed genital tuberculosis seems to exclude impregnation. There is no doubt that we find not very rarely tuberculosis of the placenta, particularly in case of general tuberculosis, which spreads to the ovum by the way of the blood. Sixty-six per cent. of his patients had never been pregnant. Thirty per cent. of the pregnancies occurred before tuberculosis manifested itself. One person in nineteen gave reasons to infer that she fell ill three weeks after confinement. Tuberculosis of other organs, heredity, and contact with tuberculous people is very important for the diagnosis. The general condition of health, the slow development of the disease, the inefficiency of any treatment as to convalescence, must be particularly looked at. Treatment is both general and local, and the author refers only to the local. Tuberculous ulcers of the ulva and vagina and of the endometrium can easily be removed. Especially attention should be paid to a complicating genorrhea and septic infection. Tuberculous diseases of the tubes and ovaries can be diagnosticated definitely only after operation. These organs should be removed when destroyed by the tuberculous process. Especial attention is to be paid to the after treatment.

8. Bacteriological Diagnosis of Typhoid. -Peabody says that of all laboratory methods in the diagnosis of typhoid fever there is none which has been used so extensively, or has given such excellent results in the hands of many clinical observers, as has the agglutination reaction. That it has been generally adopted the world over is due to its high degree of accuracy combined with its simplicity. The establishment of public laboratories, where samples of blood are examined for individual practitioners, has brought the test within the reach of a vast number of physicians. While, however, the reaction has proved itself of inestimable value, there are certain important drawbacks to its use. The chief of these is that the agglutination reaction is often late in making its appearance. It is frequently not obtained during the first week of the disease, and while it is present in about three quarters of the cases during the second week, it may be delayed much longer, and even into convalescence. Its value is, therefore, limited at the very period in the disease in which a diagnostic test is most needed; for while it is often comparatively simple to recognize typhoid fever in its later stages, it is at the onset, during the first week, that the most doubt arises, and it is in the early days of the disease that the danger of contact infection is probably greatest. Moreover, there are certain atypical cases in which the reaction is never obtained. Next to the lateness of the appearance of the agglutination test, its greatest disadvantage is that it is not absolutely specific. It does not always give an ætiological diagnosis. In the early stages of the disease, before the agglutination test is positive, the diagnosis is made in most cases by the culture; and in the later stages, when the organism can no longer be isolated from the blood, the agglutination reaction is usually present. Thus the one test is supplemented by the other, and in these two comparatively simple clinical methods—the agglutination test and the blood culture in ox bile—we have the means of making an accurate diagnosis of typhoid fever, in the great majority of cases, at any stage in the course of the disease.

16. Blood Pressure.—Eichberg concludes that the routine interrogation of the blood pressure should constitute part of the regular examination of each case. Both systolic and diastolic pressures are necessary in the solution of the problem. Systolic values of more than 130 mm. call for further study. The most important feature of the study of blood pressure is found in its behavior under tests with measured amount of work. Increase of blood pressure is often conservative, and then calls for no interference. A pressure that is at all times above normal may be the only, as it often is the earliest, evidence of arteriosclerosis.

of Three Cases, By Williams B. Cadwalader.

5. Kaolin as a Remédy, By George Richter.
6. Some Observations on the Urethral Length,
By Walter S. Reynolds.

1. Wounds of the Heart.—Hill draws the following conclusions from his own three cases and from a review of the literature: Any operation which reduces the mortality of a given injury from ninety to sixty per cent, is entitled to a permanent place in surgery, and every wound of the heart should be operated on immediately. Whenever the location of the external wound and the attending symptoms cause suspicion of a wound of the heart, it is the duty of the surgeon to determine the nature of the injury by an exploratory operation. Unless the patient is unconscious, and corneal reflex abolished, an anæsthetic should be given, and preferably chloroform. Struggling is liable to produce a detachment of a clot, and renew the hæmorrhage. Never probe the wound, as serious injury may be inflicted upon the myocardium. Rotter's operation renders access to the heart extremely easy, gives an opportunity of removing any extravasation of blood, and inspection of the pleural cavity with reference to the injuries. Steady the heart before attempting to suture it either by carrying the hand under the organ and lifting it up, or if the hole is large enough, introduce the little finger, which will serve the double purpose of stopping the bleeding and facili-

tating the passage of the stitches. When the hæmorrhage is so profuse as to preclude the possibility of suturing, with the right hand gently lift the heart out of the pericardium and introduce from below the left hand and press between the index and ring finger the vena cava inferior and its inosculation into the right atrium, and pressing upwards displace the inosculation of the vena cava superior. It has been stated that the heart will stand complete compression for a minute and a half and incomplete for four minutes. Catgut sutures should be used, as wounds of the heart heal in a remarkably short time. The sutures should be interrupted, introduced, and tied during diastole, not involve the endocardium, and as few as possible should be passed commensurate with safety against leakage, as they cause a degeneration of the muscular fibre with its tendency to dilatation and rupture. In cleansing the pericardium, it should be sponged out and no fluid poured into the sac, as quickly produced tension may cause serious consequences to an already disabled heart. Until every aseptic precaution has been taken the mechanical stoppage of the heart from accumulation of blood in the pericardium should be prevented by aspiration, as diminished resistance from loss of blood and want of cleanliness from hurry of preparation are largely contributive causes to the forty per cent. of deaths from infection. For drainage, tubes are preferable to gauze, as the latter is liable to cause retention of the discharge and may strangulate the heart. needle may be removed at once, but a knife blade must not be touched until the surgeon has bared the heart and is master of the situation, as an uncontrollable hæmorrhage might occur from premature extraction.

4. Acute Anterior Poliomyelitis.—Cadwalader reports three such cases and observes that acute anterior poliomyelitis is essentially an acute polioencephalomeningomyelitis. The process is the same during infancy and adult life and is most marked in the lumbar and cervical enlargements of the cord and frequently may extend upward as far as the cerebral cortex. Interstitial changes predominate and occur together with parenchymatous changes. Parenchymatous changes never occur without interstitial changes. The localization and intensity of cellular infiltration depend upon the distribution and vascularity of the area affected. Neuronophagia is an important factor in the destruction of ganglion cells.

By R. S. TAYLOR. I. Cerebral Aneurysms.—Bradford states that the frequency of aneurysm of the cerebral vessels is considerable when contrasted with aneurysms affecting vessels of similar size in other parts of the body. He uses the term cerebral aneurysm to describe an aneurysm which is gross and obvious to the naked eye and does not require any special methods of demonstration to show it. The cerebral vessels are peculiar anatomically in the thinness of their coats owing to the absence of any considerable amount of fibrous tissue. They are peculiar in their mode of support; they run in very large lymph channels. They are also peculiar in their physiological relationships, being very subject to high tension. The cerebral arteries are engorged passively whenever the tension rises in the systemic vessels. The vessels at the base of the brain most commonly affected by aneurysm are, first and foremost, the middle cerebral; secondly, the basilar; thirdly, the internal carotid; and, fourthly, the anterior cerebral. The aneurysms are usually saccular; false, interstitial, or dissecting aneurysms very rarely occur. The aneurysms have extraordinarily thin walls, which can possibly be correlated with the absence of any marked amount of fibrous tissue in the cerebral vessels, as compared with some vessels where aneurysms are developed elsewhere. The aneurysms are very prone to be full of blood clot, and vary enormously in size. Some of them are no larger than a pin's head, while others are almost as big as a wal-They are usually about the size of a pea. When they rupture, in the majority of cases the pia mater is not broken, and the blood is extravasated between it and the surface of the brain. Another form of rupture is where the aneurysm becomes adherent to the cerebral substance, and gives rise to intracerebral hæmorrhage which bursts into the brain and not externally. The aneurysm may not rupture, but may cause death by pressure and consequent cerebral softening. These aneurysms may occur at almost any time of life up to extreme old age, but the bulk of them occur before the fortieth year, and a very considerable proportion between the twentieth and thirtieth years. They are the result of local disease of the vessel wall, the disease being in most cases atheroma, usually of syphilitic origin. Such a syphilitic origin is more characteristic of cerebral aneurysms, than of aneurysms elsewhere. Clinically four groups of cases may be recognized:-First, those that produce no symptoms at any time, the patient dving from some other cause. Second, those where the patient simply presents the symptoms of a cerebral hæmorrhage, rapidly proving fatal. Third, where the patient presents symptoms in a greater or less degree of a cerebral tumor. Fourth, cases characterized by the following phenomena: (1) There is an early seizure followed by (2) a period in which there are no marked symptoms of any kind perhaps with the exception of some stiffness of the neck, and (3) subsequently there is a fatal seizure. Probably first of all a slight rupture occurs and then a big and fatal

rupture. It is doubtful whether aneurysm at the base of the brain can be diagnosticated with certainty, but it can be suspected. It is most likely to be confounded with a purely functional condition, the pa-

tient being thought to be neurasthenic.

3. Exophthalmic Goître.-Gullan calls attention to the following instructive facts regarding exophthalmic goitre. It mainly affects women between the ages of sixteen and forty years—i. e., at the period of sexual vitality—and is rare before puberty and after the menopause. The disease may occur in members of the same family, and, indeed, in several generations. It is often supposed to be consequent upon fright, mental shock, worry, or prolonged mental strain; or appears to date from an acute illness, such as influenza. But in most of the cases the disease has really existed before the worry or shock occurs. The thyreoid gland from a case of exophthalmic goitre shows marked changes, the cells having become columnar instead of cubical, the vesicles stellate instead of square or rounded, and a mucous substance instead of a colloid filling those vesicles. This is strongly suggestive that the goitrous change in this disease is due to a true hypertrophy, which produces an increase of the In support of the contention specific secretions. that the disease is due to excessive activity of the thyreoid (thyreoidism) is the fact that the manifestations of exophthalmic goitre are the exact opposite to those of myxœdema, which disease is undoubtedly due to a deficiency of thyreoid secretion (athyreoidism). Excessive metabolism is shown in exophthalmic goitre by the frequent, raised tension pulse, accentuated action of the heart, active and alert mental and physical condition, tendency toward elevation of the temperature, moist skin, looseness of the bowels, increased excretion of urea, and loss of body weight. It is probable that the normal function of the thyreoid is detoxication of metabolic The intimate relation which exists beproducts. tween the thyreoid and the generative organs-the gland often swells at the menstrual period, involutes or atrophies at the menopause, causing myxœdema, hypertrophies at puberty or during pregnancy, causing exophthalmic goître-inclines the writer strongly to the view that some abnormality in the function of the generative organs may be the starting point of the thyreoid derangement. It is improbable that parathyreoid insufficiency has anything to do with exophthalmic goitre.

4. Spinal Analgesia. - Renton reports fifty consecutive operations in which spinal analgesia was carried out, and gave great satisfaction. The procedure has been greatly improved of late by the use of an injection compound of greater specific gravity than the cerebrospinal fluid. The heavy compound travels to the lowest part of the spinal canal, and by moving the patient or shifting his position, the height of analgesia can be definitely controlled. The position of the patient is one of the most important factors in the success of the method. The patient lies on the side to be operated on, and the knees are fully flexed on the abdomen. The head and neck must always be raised. Only a slight elevation of the pelvis is necessary. Puncture can be done between either the third and fourth, or second and third lumbar spines. As a rule two or three

drachms of cerebrospinal fluid should be removed before making the injection. The compound used consists of stovaine, five grains; glucose, five grains; and sterilized water to one hundred minims. One cubic centimetre (seventeen minims) is used each time, of which two minims remain in the needle. Of course strict asepsis is essential to the safety of spinal analgesia. Abdominal relaxation is perfect, and no straining can take place, as the abdominal muscles are paralyzed. Cutting of the peritonæum is painless, but traction causes discomfort and nausea. Acute abdominal cases do extremely well. In hæmorrhoid and perineal cases the puncture is done in the sitting position, and the effect of the heavy compound is well seen, only analgesia of the perineal region resulting, the legs and abdomen remaining unaffected. The procedure is most satisfactory in hernias, the relaxation of the muscles being perfect. The same is true of operations on the extremities. Out of fifty cases there were two failures to puncture, and insufficient analgesia in three. In the latter failure was probably due to the compound having been injected outside the dural sac. The longest operation performed lasted eighty minutes. No bad results of any kind developed afterward in any of the cases. Nervous patients usually prefer general anæsthesia, but spinal analgesia is better in cases of arteriosclerosis, of old age, of alcoholism, and in certain acute abdominal conditions.

By Labbe and G. Vitry.
3. Graphic Electrodiagnosis. Its Importance in Accidents
Among Workmen,
By J. Larat.
By J. Larat.

- r. Deformity of the Pelvis in Lumbar Scoliosis.—Desfosses presents fourteen plates which illustrate the deformities found in pelves of patients suffering from scoliosis. He says that beyond doubt the inequality in the volume of the pelvis is due in part to the displacement of the lumbar vertebræ. Nevertheless, this inequality of volume is very often absolutely real and corresponds not only to a diminution of the volume of the soft parts, but to an arrest of development of the pelvis on the side of the convexity of the lumbar column.
- 2. The Urinary Sulphoethers. Labbe and Vitry declare that in the present state of our knowledge the relation of the sulphoethers to the total urinary azote is destitute of clinical signification.

The Lipoids,
 Present State of Antitetanic Serum Therapy,
 By L. Lagane.

1. The Lipoids.—Iscovesco divides the lipoids into three classes based on their biochemical properties. One class of these bodies, particularly lecithine, has the property of forming extremely toxic compounds by uniting with certain substances, other lipoids are toxic themselves and differ from the true toxines in their resistance to heat and in their solubility, while a third possesses the property of neutralizing various biological toxic agents. The latter include the antitoxines, or antihæmolysines, or bactericide substances.

By KRAUSE and KLUG. 12. Experiments with Various Derivatives of Tubercle Ba-cilli (Concluded). By A. WOLLFF-EISNER. cilli (Concluded).

1. Plastic Repair of Traumatic Defects of the Auricle.—Schmieden reports two cases. In the first he replaced the lobe of the ear, the lower part of the helix, by means of a skin flap taken from the upper arm. In the second the entire auricle was gone, and the operation was rather complex. A portion of the cartilage of the rib cut into the shape of the cartilage of the ear was taken out and implanted with its perichondrium under the skin of the breast. Second, a large skin flap was formed with its base below the clavicle, containing the piece of cartilage. Third, the flap was freed so that its pedicle was on the clavicle, the scar about the auricular opening was excised, the graft applied and secured with sutures, while the head was bent over to meet it and retained in position, with the arm going over the head by a plaster bandage. Fourth, the graft was cut free from the breast. Fifth, a posterior surface was formed for the graft from a flap taken from the skin of the head.

2. The Adrenal System and the Kidneys .-Reicher states that it is very probable that the adrenal secretion and the internal relations between the adrenal system and the kidneys has a weighty pathogenic importance in many forms of nephritis.

5. Experimental Studies Concerning the Fulguration of Vital Organs.-Arndt and Laqueur thus sum up the results of their experiments: Deep narcosis is not absolutely necessary for the fulguration treatment so long as the skin remains outside the field of the sparks or is protected from them. Fulguration of the skin causes a little irritation, that of the muscles and bones no noticeable effect upon the heart and respiration. 2. Fulguration may be applied to the brain and dura mater even for a considerable time without immediate injurious consequences. Minor irritative effects, which in fulguration of the dura may be ascribed to increase of the blood pressure, may be avoided by use of short sparks. 3. Fulguration of the thoracic organs must be made only with certain precautions, as the heart reacts immediately to the sparks with anythmia and

lowering of the blood pressure, and is only slightly protected by the pericardium. This injury is particularly great in bipolar application of the fulguration. Carbonic acid cooling is to be avoided in fulguration of the internal organs of the thorax. Fulguration of the digestive tract and of the bladder calls forth strong peristalsis and contraction, but only by the direct application of the sparks. The skin of the abdomen or dry compresses afford a certain protection against this action. 5. Immediately after the fulguration pieces of tissue and tumors show no injury aside from a little superficial necrosis. 6. The physiological action of direct monopolar application of the high frequency current is in many respects the same as that of fulguration and is sometimes better. This shows that the effect of fulguration is not wholly due to the discharge of the sparks, but that the high frequency current is also a factor.

8. Action of Hydrochloric Acid.—Ehrmann and Lederer assert that the statement made by Pawlow that hydrochloric acid was a specific excitant of

the pancreas is incorrect.

11. A Rare Disturbance after Submucous Resection of the Nasal Sæptum,

By MÜLLER By SAALFELD 12. Obituary of Oskar Liebreich,

1. Clinical Diagnosis of Sclerosis of the Pulmonary Artery.-Posselt discusses the question under what circumstances is a clinical diagnosis of stenosis of the pulmonary artery possible, and comes to the conclusion that: A. With a primary mitral stenosis and in the presence of the subsequent symptom complex it may be made with the greatest probability, 1, by the physical examination which reveals a zone of dulness over the upper left margin of the sternum with tenderness to pressure and percussion, especially in certain positions, an unusual extension of the cardiac dulness to the right, the x ray picture of the upper part of the middle arch, and gradual extension outwards of the diastolic thrill and of the diastolic (presystolic) murmur towards the pulmonary orifice; 2, by clinical symptoms; marked cyanosis as an early symptom and the great difference lasting a long time between this and either absent or slight dyspnœa, ædema, and other symptoms of stasis; onset of attacks of dyspragia intermittens angiosclerotica pulmonalis (angina hypercyanotica); absence of the formation of drumstick fingers in spite of the high degree of cyanosis; repeated large pulmonary hæmorrhages without pronounced infarct character. B. Accurate observation of the preceding makes also possible the recognition of the extremely rare primary pulmonary sclerosis. C. When the pulmonary sclerosis appears with sclerosis and insufficiency of the semilunar valves of the aorta, which is very rarely combined with it, there are some peculiarities which form an indication of diagnostic value. Such are the marked cyanosis instead of the pale facies aortica to be expected, a hypertrophy of the right heart not explained by other causes, and an abnormal direction of the diastolic murmur to the left.

2. Changes in the Nervous System after Stovaine Anæsthesia.-Spielmeyer found by experiments on dogs that degenerative changes were apt to persist in the cells of the nervous system, but concludes that, as in one group of cases in which only 0.05 to 0.07 of stovaine was given, no characteristic cell changes could be detected, possibly the reduction of the dose may abate the chances of the onset of

changes in the nervous system.

5. Carrot Soup in Nutritive Disturbances of Infants.-Moro recommends highly carrot soup as a diet for sick infants, contraindicated only in cases where the child is ædematous and where the nutritive disturbance has been occasioned by an exclusive or disproportionate carbohydrate diet.

- 6. Resorption of Antitoxine through the Rectum.—Hamburger and Monti found that in only one out of twenty-four cases in which the method was tried was there an evident result from the rectal application of serum. They therefore conclude that in man tetanus antitoxine, and probably other antitoxines, rubbed into the rectum usually fail to be resorbed.
- 11. A Rare Disturbance after Submucous Resection of the Sæptum.-Müller reports a case in which, after submucous resection of the sæptum, the patient was annoyed by a whistling sound in his nose during respiration. This was found to be due to a tense fold of membrane at the edge of an aperture two millimetres in diameter visible only in the left cavity.

The Modern Babies' Dispensary.—Gustenberger says an ideal institution ought to comprise the following elements: 1, A dispensary to which mothers could bring both healthy and sick babies soon after birth, get proper instructions, and have her history recorded, also in which nurses, students, and physicians could get proper training. The person in charge should ascertain whether any given applicant is worthy, and the dispensary should cooperate with other institutions, find mothers for babies, and homes for both. There should be a waiting room, a weighing room, examining rooms, a room for minor surgery, isolation rooms, lecture room, and clinical laboratory. 2, A milk laboratory

to supply clean milk in pints and quarts, or in suitable nursing bottles, and where food could be pasteurized and sterilized. 3, A hospital for sick babies with all suitable furnishings and for the working out of pathological problems. 4, An isolation house for contagious disease. 5, Branch dispensaries in the crowded districts, to be supplied with milk from the central establishment and to send their sick to the central hospital. 6, Convalescent homes and fresh air camps in the country.

2. Dental Caries as a Cause of Disease in Children.—Herrmann states that in rickets, syphilis, and tuberculosis we have examples of constitutional disease which may cause characteristic changes in the teeth. Scurvy, diabetes, and leuchæmia also show characteristic conditions in the month. It is believed that these and many distinctly oral diseases could be studied with advantage by physician and dentist in conjunction. Cause and effect must not be confounded in the analyses of constitutional diseases associated with oral changes. The changes may be primary, but they frequently represent only one manifestation of the oral condition. The following are cited as diseases which may result from an abnormal condition of the teeth: I, Diseases of the tooth itself. 2, Diseases of adjacent structures, gingivitis, pyorrhœa alveolaris, alveolar abscess, periostitis, ostitis, necrosis. 3, Different forms of stomatitis, including ulcerative and gangrenous stomatitis and tonsilitis. 4, Diseases of the maxillary sinuses. 5, Diseases of the cervical lymph nodes, cellulitis (Ludwig's angina). 6, Diseases of the alimentary tract. 7, General infections, septicæmia, pyæmia. 8, Diseases of the blood, disturbances of nutrition, nervous diseases.

3. The Distribution of Bacteria in Bottled Milk and its Application to Infant Feeding .-Hess summarizes his paper in the following conclusions: In bottled milk the bacteria are by far the most numerous in the upper layers of the cream, becoming gradually less numerous in the lower portion. The upper two ounces contain the greatest number of bacteria. This is true of tubercle bacilli as well as of streptococci and other bacteria. Instead of using the upper cream it is therefore safer to discard the upper two ounces. The average bottle of such partially skimmed milk contains three per cent. fat, and three and five tenths per cent. proteid, and is well adapted for infant feeding. Discarding the upper two ounces we then have seven ounces of twelve per cent. milk, then eight ounces of ten per cent. milk, then twelve ounces of seven per cent. milk. The usual top milk formulæ may be prepared with these figures as a basis.

Treatment of Undescended or Maldescended Testis Associated with Inguinal Hernia.--Coley thinks the following conclusions justifiable: 1. The organ is usually of little or no functional value. It is more subject to inflammation and pain than the normally placed testis, and may be more subject to malignancy. 2. It should never be sacrified in children and rarely in adults in operating for radical cure of hernia. It is valuable in developing the male characteristics of a child and in promoting his general health. It should be saved in the adult on account of the influence on the patient's mentality. 3. Operation should seldom be performed earlier than the age of eight to twelve unless the hernia demands intervention. The testis may descend spontaneously as puberty approaches. Abdominal ectopia should remain untreated unless double. eration requires free opening of the inguinal canal by Bassini's incision, freeing the testis from adhesions and bands, bringing it into the scrotum, and suture of the canal without transplantation of the The removal of any of the structures of the cord is seldom indicated. 5. No case of double un-descended testis should be allowed to reach the age of puberty.

b. Hæmaturia as a Complicating Factor in Appendicitis.—Seelig thinks the following classification of cases of this condition is appropriate: I. Cases of hæmaturia due to the action of toxines upon the kidneys. 2. Cases due to direct involvement of the kidneys. 3. Cases due to direct involve-ment of the ureter. 4. Cases in which the urinary bladder has been perforated by an appendicular abscess, one of the resulting symptoms being blood in the urine. In other words, hæmaturia complicating appendicitis may be due to general systemic invasion resulting from acute appendicitis and affecting the kidney indirectly, toxic nephritis, direct involvement of the kidney or ureter, or the urinary

bladder.

Volkmann's Ischæmic Paralysis.—Taylor finds that this is essentially a myositis resulting from prolonged deprivation of oxygenated blood. muscle substance is replaced by fibrous tissue, varying in quantity and degree, of resulting contracture with the severity of the case. The nerves may be involved from the ischæmia and pressure, or from compression by the cicatricial mass. Most of the cases occur in children as the result of too tight dressings, especially when applied for fractures near The diagnostic symptoms are pain, the elbow. swelling, and simultaneous appearance of rigid contracture and paralyzed muscles. The condition may occur after six hours of tight compression. phylaxis is all important, no tight dressings being used for fractures, especially when near the elbow Allowance must be made for traumatic reactionary swelling, and dressings frequently in-

Should the lesion occur, dressings must be removed and effort made by massage, electricity, etc., to restore muscle function. Should this fail a more or less extensive operation upon the tendons or bones will be required, which must be followed by a careful course of physical therapeutics. The prognosis is unfavorable, a cure may be deferred for months or years.

Remarks on the Importance of Early Sur-5. Treatment of Gallstone Disease.-Gavin gical states that to properly diagnosticate gallstone disease we cannot lay too much stress upon the importance of taking a careful history of the early symptoms of the disease; the gallbladder being in apposition with so many other important organs, any inflammatory trouble of a few weeks' duration will involve another organ; thereby changing greatly all of the symptoms; hence the importance of the early history. We generally find the affected gallbladder in one of three conditions: (1) Cholecystitis without stone is really a more serious condition than with stone; as we know, the more virulent the infection the less likely we are to have stone formation. The main symptoms in this condition are, a slow type of fever, a dull aching pain in the epigastrium, with distinct tenderness on pressure which lasts several days and passes off gradually; always more or less fever present. (2) Cholecystitis with stone may be subdivided into (a) those cases where the gallstones are confined to the gallbladder, and give rise to the intermittent attacks of gallstone colic; (b), those cases where stones have passed out into the cystic duct; and (c), those cases where the stones are lodged in the common duct. (a) Given a case with a history of acute attacks of severe colic in the right side of the upper abdomen, coming on at irregular intervals, not being caused by anything that has been taken into the stomach, passing off as a rule suddenly, either by vomiting, rumbling of gas, or taking an opiate, and followed by a quick return to normal health, we are dealing with cholecystitis with the stones confined in the gallbladder. (b) Given a case, with the history of one or more of the attacks, coming on suddenly and passing off quickly, but after this attack the patient is found complaining of more or less tenderness

over the gallbladder, has a temperature of 100° F. or 102° F., coated tongue, skin of a "bilious" hue, and a constant aching in the upper abdomen, as though he might at any time have another attack of the severe colic, then we are dealing with a stone in the cystic duct and the small lymphatic gland at the junction of the cystic and common ducts is involved. (c) Given a case, with a history of previous attacks, as related, with a distinct jaundice, that some days is more prominent than others, with all kinds of symptoms referable to the gastrointestinal tract, and we are dealing with cholecystitic with stone formation in the common duct. (3) Cholecystitis with contraction of the gallbladder is really a later result where the organ has safely withstood the onslaught of many attacks of acute cholecystitis, and we may find stones present or not. All cases of gallstone disease, if not operated on, will terminate in one of three ways: (1) Rupture that may cause diffuse peritonitis, or enter the alimentary tract. (2) By adhesions to the surrounding organs, causing such distortion of the tissues that we have slow emaciation from indigestion, and often a secondary ulceration of the stomach or duodenum. (3) By developing malignancy.

Meeting of April 16, 1908.

The President, Dr. John A. Wyeth, in the Chair.

The Pathological Changes in the Thyreoid Gland as Related to the Varying Symptoms in Graves's Disease; Based on the Pathological Findings in 275 Cases of Exophthalmic Goître.— Dr. Louis B. Wilson, of Rochester, Minn., read this paper, illustrating it with lantern slide projections and stereopticon views. He said the material for the study had been obtained from operations and autopsies in cases of hyperthyreoidism (exophthalmic goître) in St. Mary's Hospital, Rochester, Minn., from March 3, 1898, to April 10, 1908. The series consisted of: (a) Eleven cases in young females whose symptoms had existed without remission or abatement from two months to two years, but who at the time of examination presented all the classic symptoms of Graves's disease in a severe form. The pathological diagnosis in all these cases was that of typical exophthalmic goître. (b) Nine cases in females whose symptoms had existed from one to eleven years, but all of whom were better at the time of examination than they had been at some previous period. In all these cases the pathological report was either of typical exophthalmic goitre or exophthalmic goitre with colloid. Fourteen cases in females whose symptoms had been present from three to thirty years, or from three months to a year following a previous long period of nonsymptomatic goitre, and at no time had shown symptoms of more than moderate severity. The pathological report in these cases was that of colloid adenoma. All specimens were brought persodiately from the operating room to the laborators, where the were examined fresh and then placed in fixatives, usually within ten minutes after they were removed from the patients. The histology in each case was carefully reviewed from all the preparations at hand, and notes made according to a formula compiled from the reports of previous observers. While this review was in progress every care was taken to exclude all knowledge of the clinical histories of the cases, in order that there might be no clinical bias entering into the pathological estimate. As the work progressed it was found that certain pathological pictures were repeating themselves with monotonous frequency. When the examinations were completed these pictures were found to represent cases constituting four large natural groups, and there was little trouble in arranging the remainder of the cases so as to form connecting groups between the large and more striking ones. On the basis of this grouping, which was from study of the specimens alone, and on the working hypothesis that Graves's symptoms arose from increased absorption of thyreoid secretion, Dr. Wilson ventured to make a conjecture of the probable clinical history in each case. This was an attempt to determine in as unbiased a manner as possible whether or not there existed any definite relationship between the varying pathological changes in the thyreoid gland and the varying symptoms in Graves's disease. For determining the value of these conjectures, Dr. H. S. Plummer, who had written the original office histories in the majority of the cases, kindly reviewed his own histories, as well as those of the other clinicians, and grouped them as follows: Grade I. Acute cases of mild, moderate, severe, or very severe degree. Grade 2. Cases which had been severe but at the time of examination showed remission of symptoms. Grade 3. Cases of previously severe hyperthyreoidism, but with symptoms now chiefly of severe vital organ lesion type (heart, nervous system, etc.) rather than hyperthyreoidism. Grade 4. Mild continuous cases slowly developing. When the clinical and pathological classifications had been definitely made, the two were compared case by case. He then presented and described a few stereoscopic photographs of Graves's thyreoids. The following pathological grouping was presented:

PATHOLOGICAL GROUP A.

- 1. Small Intraalveolar Parenchyma Increase.
 - a. Size of gland.
 - b. Increased number of cells in a single layer.
 - c. Reduplication of layers.
- 2. Small Amount of Thin Secretion. Shown by
 - a. Dryness of fresh specimen.
 - b. Small amount of secretion in stained sections. This is noneosine staining.

Pathological Group B.

- t. Large Intraalveolar Parenchyma Increase. Shown by
 - a. Size of gland.
 - b. Increased number of cells in a single layer.
 - c. Reduplication of layers.
 - d. Infolding of alveolar walls.
 - a Papilla formation,

2. Large Amount of Thin Secretion.

Shown by

a. "Glair" of fresh section.

b. Large amount of secretion, which is noneosine staining in stained sections.

PATHOLOGICAL GROUP C.

I. Large Intraalveolar Parenchyma Increase. Shown by

a. Size of gland.

b. Increased number of cells in a single layer.

c. Reduplication of layers. d. Infolding of alveolar walls.

e. Papillæ formation.

2. Large Amount of Thin Secretion.

Shown by

a. "Glair" of fresh section.

b. Large amount of secretion, most of which is noneosine staining in stained sections.

3. Beginning Degeneration.

Shown by

a. Denser staining of some of the secretion.

b. Beginning exfoliation of parenchyma.

PATHOLOGICAL GROUP D.

I. Old Intraalveolar Parenchyma Increase.

Shown by

a. Size of gland.

b. Remains of infolding.

c. Remains of papillæ.

2. Large Amount of Thick Secretion.

Shown by

a. Gelatinous appearance of fresh secretion.

b. Large amount of secretion, most of which is eosine staining in stained sections.

3. Advanced Degeneration.

Shown by

a. Dense staining of most of the secretion.

b. More or less complete exfoliation of the parenchyma.

PATHOLOGICAL GROUP E.

I. Small Multialveolar Parenchyma Increase. Shown by

a. Size of gland.b. Recently formed alveoli.

2. Small Amount of Thin Secretion.

Shown by

a. Dryness of fresh secretion.

b. Small amount of secretion, which is noneosine staining in stained sections.

PATHOLOGICAL GROUP F.

I. Large Multialveolar Parenchyma Increase. Shown by

a. Size of gland.

b. Recently formed alveoli.

2. Large Amount of Thin Secretion. Shown by

a. "Glair" of fresh secretion.

b. Large amount of secretion, which is noneosine staining in stained sections.

PATHOLOGICAL GROUP G.

1. Large Multialveolar Parenchyma Increase. Shown by

a. Size of gland.

b. Recently formed alveoli.

2. Large Amount of Secretion.

Shown by

a. Large amount of secretion, most of which is noneosine staining in stained sections.

3. Beginning Degeneration.

Shown by

a. Denser staining in some of the secretion.

b. Beginning exfoliation of parenchyma.

PATHOLOGICAL GROUP H.

1. Old Multialveolar Parenchyma Increase. Shown by

a. Size of gland.

b. Sometimes scattered groups of recently

2. Large Amount of Thick Secretion.

Shown by

a. Gelatinous appearance of fresh section.
